## Royal Society Esso Award

Rp385

## for the Conservation of Energy

The Royal Society Esso Award for 1975 has been made jointly and equally to Professor H. C. Hottel of the Massachusetts Institute of Technology and Professor H. Tabor of the Israel Scientific Research Foundation. The Award has been made to Professor Hottel for work on problems of solar energy utilisation, particularly in solar-heated houses. Professor Tabor received the Award for his work on the theory of selective surfaces, also on increasing efficiency of solar energy collectors, including the design of focusing collectors, and the development of turbines for operation on solar energy.

The Royal Society Esso Award for the Conservation of Energy was instituted in 1974 and consists of a gold medal and a prize of £1,000 offered for outstanding contributions to the advance of science, engineering or technology, leading to the more efficient conversion or use of any form of energy. **Nominations for the 1976 Award are required by 2 February 1976.** For further details, please contact  
The Executive Secretary, The Royal Society,  
6 Carlton House Terrace, London SW1Y 5AG.

- L-leucine, a specific inhibitor of a rare human placental alkaline phosphatase phenotype—G. J. Doellgast and W. H. Fishman 49
- Late acquisition of a germ line antibody specificity—N. H. Sigal, P. J. Gearhart, J. L. Press and N. R. Klinman 51

## Guide to authors

● Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.

● Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).

● 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the *Système International*. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible,  $\exp(a)$  is preferred to  $e^a$  if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript. All artwork should be marked with the author's name. Line drawings should preferably be in Indian ink on heavy cartridge paper, although other materials are acceptable: thin, shiny, folded, torn or heavily handled material should be avoided. Matt rather than glossy photographs are preferred. Figures are usually reduced to one column width. The originals should be about as wide as a page of *Nature*. Figures, particularly maps, should contain nothing but essential material. It is preferred that the original be unlabelled, but with a copy containing lettering. Labelling on photographs should if possible be avoided entirely. We are always glad to see artwork for possible use on the cover, whether or not it is associated with a manuscript, but cannot guarantee the return of material.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

A fuller guide appeared in *Nature* (246, 238; 1973)

Classical pathway activation of complement system by IgA anti-C3 antibody— <i>B. D. Williams, J. M. Slaney, J. F. Price and S. J. Challacombe</i>	52
Antibodies against homogeneous epoxide hydratase provide evidence for a single enzyme hydrating styrene oxide and benz(a)pyrene 4,5-oxide— <i>F. Oesch and P. Bentley</i>	53
Complexity of germline and somatic DNA in <i>Ascaris</i> — <i>K. B. Moritz and G. E. Roth</i>	55
No detectable satellite DNA in supernumerary chromosomes of the grasshopper <i>Myrmeleotettix</i> — <i>G. A. Dover and S. A. Henderson</i>	57
Mechanism of differential Giemsa method for sister chromatids— <i>T. Sugiyama, K. Goto and Y. Kano</i>	59
Thermolabile transfecting DNA from temperature-sensitive mutant of phage 29— <i>S. Yanofsky, F. Kawamura and J. Ito</i>	60
Involvement of DNA in resistance of potatoes to invasion by <i>Phytophthora infestans</i> — <i>M. Yamamoto and K. Matsuo</i>	63
New class of enzymes acting on damaged DNA— <i>T. Lindahl</i>	64

## BOOK REVIEWS

A Survey of the Almagest (Olaf Pederson)— <i>R. P. Lorch</i>	67
Solar, Gamma-, X- and EUV Radiation (Sharad E. Kane)— <i>C. G. Rapley</i>	68
The Evolution of an Evolutionist (C. H. Waddington)— <i>T. H. Jukes</i>	68
The Human Conspiracy (Nigel Calder and BBC Television)— <i>N. S. Sutherland</i>	69

Relevance of oxygen ligands to reduction of ligating dinitrogen— <i>J. Chatt, A. J. Pearman and R. L. Richards</i>	204
Elevation of selenium levels in air by xerography— <i>J. M. Harkin, A. Dong and G. Chesters</i>	204
Do birds use waves for orientation when migrating across the sea?— <i>T. Alderstam and S.-G. Pettersson</i>	205
Oscillations of tropical insect populations— <i>M. Bigger</i>	207
Divergent X-ray-induced mutation rates in the mouse for <i>H</i> and "7-locus" groups of loci— <i>H. I. Kohn and R. W. Melvold</i>	208
Specific marker chromosome 14 in malignant lymphomas— <i>S. Fukuhara, S. Shirakawa and H. Uchino</i>	210
Examination of ATCC stocks for HeLa marker chromosomes in human cell lines— <i>K. S. Lavappa, M. L. Macy and J. E. Shannon</i>	211
Vertical transmission of tumour resistance in guinea pigs— <i>M. A. Wanberg, P. Minden and D. W. Weiss</i>	213
Gene that controls initiation of chromosome replication and prophage induction in <i>Bacillus subtilis</i> — <i>S. Murakami, S. Muiakami and H. Yoshikawa</i>	215
Differentiation of B and T mouse lymphocytes in cell suspension and smears— <i>M. Padnos</i>	218

**Guide to authors**

● Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.

● Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).

● 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the *Système International*. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, exp (a) is preferred to e<sup>a</sup> if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

**Artwork** should be sent with the manuscript. All artwork should be marked with the author's name. Line drawings should preferably be in Indian ink on heavy cartridge paper, although other materials are acceptable: thin, shiny, folded, torn or heavily handled material should be avoided. Matt rather than glossy photographs are preferred. Figures are usually reduced to one column width. The originals should be about as wide as a page of *Nature*. Figures, particularly maps, should contain nothing but essential material. It is preferred that the original be unlabelled, but with a copy containing lettering. Labelling on photographs should if possible be avoided entirely. We are always glad to see artwork for possible use on the cover, whether or not it is associated with a manuscript, but cannot guarantee the return of material.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

A fuller guide appeared in *Nature* (246, 238; 1973).

Inhibitory effect of dibutyryl cyclic AMP and theophylline on the aggregation of human breast tumour cell line BT-20— <i>R. Tchao and J. Leighton</i>	220
Abortogenic activity of antiserum to alpha-fetoprotein— <i>G. J. Mizejewski and P. M. Grimley</i>	222
Early production of intracellular IgM by B-lymphocyte precursors in mouse— <i>M. C. Raff, M. Megson, J. J. T. Owen and M. D. Cooper</i>	224
Resistance of activated macrophages to H-2 antibody-mediated cytotoxicity and Fc rosette inhibition— <i>R. S. Kerbel</i>	226
H-2-like specificities of foreign haplotypes appearing on a mouse sarcoma after vaccinia virus infection— <i>F. Garrido, V. Schirmacher and H. Festenstein</i>	228
Surface membrane alterations in somatic cell hybrids of neuroblastoma and glioma cells— <i>M. C. Glick, Y. Kimhi and U. Z. Littauer</i>	230
Tumour promotor induces plasminogen activator— <i>M. Wigler and I. B. Weinstein</i>	232
Evidence for inhibition of platelet activation in blood by a drug effect on erythrocytes— <i>G. V. R. Born, D. Bergquist and K.-E. Arfors</i>	233
Inhibition of plasmin-mediated fibrinolysis by vitamin E— <i>L. A. Moroz and N. J. Gilmore</i>	235
Confusion between specific and nonspecific binding of carcinoembryonic antigen and blood-group antigens by eluted antibody preparations— <i>G. Taylor and D. L. J. Freed</i>	237
Active proton transport stimulated by CO <sub>2</sub> /HCO <sub>3</sub> <sup>-</sup> , blocked by cyanide— <i>W. F. Boron and P. De Weer</i>	240
The presence of Na-Na and Na-K exchange in sodium extrusion by three species of fish— <i>D. H. Evans and K. Cooper</i>	241
Roles of carbonyl oxygens at the bilayer interface in phospholipid-sterol interaction— <i>C.-H. Huang</i>	242
Effect of prostaglandin synthesis on renal function and renin in the dog— <i>P. M. Bolger, G. M. Eisner, P. W. Ramwell and L. M. Slotkoff</i>	244
Interaction of tryptophan transfer RNA with Rous sarcoma virus 35S RNA— <i>J. J. Eiden, K. Quade and J. L. Nichols</i>	245
11- <i>cis</i> vitamin A in dark-adapted rod outer segments is a probable source of prosthetic groups for rhodopsin biosynthesis— <i>C. D. B. Bridges</i>	247

**Corrigendum**

248

**Matters arising**

Chinese cosmology— <i>N. Sivin</i>	249
Moinian and Lewisian of Sutherland and the Moravian Orogeny— <i>S. J. Moorhouse and V. E. Harrison</i>	249
Evolutionary changes in insulin— <i>T. H. Jukes</i>	250
Specificity of transfer factor— <i>M. R. Salaman and H. Valdimarsson</i>	250
Insectivorous grouse?— <i>R. Moss and A. Watson</i>	250
Temperature, phenoxybenzamine and adrenoceptor transformation— <i>G. Kuros and M. Nickerson</i>	251
Reply— <i>B. G. Benfey</i>	252
<i>Aedes aegypti</i> complex in Africa— <i>H. E. Paterson, C. A. Green and R. J. Mahon</i>	252
Reply— <i>J. A. Scott and G. A. H. McClelland</i>	252

**BOOK REVIEWS**

Sociobiology: The New Synthesis (E. O. Wilson)— <i>V. C. Wynne-Edwards</i>	253
The Superconducting State (A. D. C. Grassie)— <i>David Dew-Hughes</i>	254
Insect Biochemistry and Function (D. J. Candy and B. A. Kilby, editors)— <i>A. L. Devonshire</i>	254
Enzyme Kinetics: Behaviour and Analysis of Rapid Equilibrium and Steady-State Enzyme Systems (I. H. Segal)— <i>S. E. Halford</i>	255
Principles of Comparative Respiratory Physiology (P. Dejours)— <i>T. A. Sears</i>	255
Electron Densities in Molecules and Molecular Orbitals (J. R. van Wazer and I. Wazer)— <i>D. H. Whiffen</i>	255

Differential function of major histocompatibility complex antigens in T-lymphocyte activation—F. H. Bach, M. L. Bach and P. M. Sondej	273
---	-----

## ARTICLES

Two origins of replication in composite R plasmid DNA—D. Perlman and R. H. Rownd	281
Replication control in a composite plasmid constructed by <i>in vitro</i> linkage of two distinct replicons—F. Cabello, K. Timmis and S. N. Cohen	285

## LETTERS TO NATURE

Can 'invisible' bodies be observed in the Solar System?—M. E. Bailey	290
Third discontinuity in the Vela pulsar period—R. N. Manchester, W. M. Goss and P. A. Hamilton	291
B-emission stars and X-ray sources—L. Maraschi, A. Treves and E. P. J. van den Heuvel	292
Does Mercury have a molten core?—P. E. Fricker, R. T. Reynolds, A. L. Summers and P. M. Cassen	293
Mid-latitude ionospheric scintillation fading of microwave signals—W. E. Brown, III, G. G. Haroules and W. I. Thompson, III	294
Long conductors as antennae for gravitational radiation—R. J. Adler	296
Palaeozoic and Mesozoic age trends for some ring complexes in Niger and Nigeria—P. Bowden, O. Van Breemen, J. Hutchinson and D. C. Turner	297
Age of the migmatization in the Dalradian of Shetland—D. Flinn and I. R. Pringle	299
Simultaneous measurements of H <sub>2</sub> O, NO <sub>2</sub> and HNO <sub>3</sub> in the daytime stratosphere from 15 to 35 km—J. E. Harries, D. G. Moss, N. R. W. Swann, G. F. Neill and P. Gildwarg	300
Search for correlation between geomagnetic disturbances and mortality—B. J. Lipa, P. A. Sturrock and E. Rogot	302
Hardy-Weinberg ratios and rare male mating advantage—L. Nunney	304
Energetic cost of locomotion in Australian hopping mice—T. J. Dawson	305
Mutants of <i>Klebsiella pneumoniae</i> resistant to several antibiotics—H. Williams Smith	307
Selective entry of immunoblasts into gut from intestinal lymph—J. Hopkins and J. G. Hall	308
Protection of mice against <i>Babesia</i> and <i>Plasmodium</i> with BCG—I. A. Clark, A. C. Allison and F. E. Cox	309
Contact-induced spreading is a new phenomenon depending on cell-cell contact—C. A. Middleton	311
Chronic suppression of immunoglobulin allotype production in adult congenic mice—M. J. Bosma and G. C. Bosma	313
Decreased resistance in some heterozygotes in H-2-linked response to polyoma-induced tumour—D. Oth, F. Robert, M. Berebbi and G. Meyer	316
S <sub>1</sub> routing of synapses after partial denervation of frog cardiac ganglion—K. Courtney and S. Roper	317
Molecular differentiation in the preimplantation mouse embryo—J. Van Blerkom, S. C. Barton and M. H. Johnson	319
Increased cyclic nucleotide phosphodiesterase activity in leukaemic lymphocytes—W. N. Hait and B. Weiss	321
S <sub>1</sub> electrophotometric evidence for the presence of phytochrome in the envelope membranes of barley etioplasts—A. Evans and H. Smith	323
Regulation of RuDP carboxylase/oxygenase activity and its relationship to plant photorespiration—S. D. Kung and T. V. Marsho	325

### Guide to authors

● Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.

● Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).

● 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

**Manuscripts** may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the *Système International*. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, *exp* (*a*) is preferred to *e<sup>a</sup>* if '*a*' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

**References** are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

**Artwork** should be sent with the manuscript. All artwork should be marked with the author's name. Line drawings should preferably be in Indian ink on heavy cartridge paper, although other materials are acceptable: thin, shiny, folded, torn or heavily handled material should be avoided. **Guide to authors**

● Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.

● Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).

● 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the *Système International*. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible,  $\exp(a)$  is preferred to  $e^a$  if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

'(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript. All artwork should be marked with the author's name. Line drawings should preferably be in Indian ink on heavy cartridge paper, although other materials are acceptable: thin, shiny, folded, torn or heavily handled material should be avoided. Matt rather than glossy photographs are preferred. Figures are usually reduced to one column width.

The originals should be about as wide as a page of *Nature*. Figures, particularly maps, should contain nothing but essential material. It is preferred that the original be unlabelled, but with a copy containing lettering. Labelling on photographs should if possible be avoided entirely. We are always glad to see artwork for possible use on the cover, whether or not it is associated with a manuscript, but cannot guarantee the return of material.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

A fuller guide appeared in *Nature* (246, 238; 1973).

Loss of a non-histone chromatin protein parallels <i>in vitro</i> differentiation of cartilage— S. A. Newman, J. Bunbaum and G. C. T. Yeoh	417
Expression of parental histone genes in the intergeneric hybrid <i>Triticale hexaploide</i> — S. Spiker	418
Transbilayer movement of cholesterol in dipalmitoyllecithin-cholesterol vesicles— M. Poznansky and Y. Lange	420
Identification of $\beta$ carbolines isolated from fluorescent human lens proteins— J. Dillon, A. Spector and K. Nakanishi	422
Light-induced fast conformational change in all- <i>trans</i> -retinal at low temperature— S. Georgiou	423
Erratum	424
Matters arising	
Algal sexuality—P. Heywood	425
Irradiation and DNA breaks—B. S. Srivastava	425
Reply—I. Johansen and E. Boye	426
Scrotal asymmetry in man and in ancient sculpture—I. C. McManus	426

## ARTICLES

Head-tail radio sources in the cluster of galaxies Abell 1314— <i>J. P. Vallée and A. S. Wilson</i>	451
T4 gene 32 protein model for control of activity at replication fork— <i>H. Moise and J. Hosoda</i>	455
Body weight, diet and home range area in primates— <i>K. Milton and M. L. May</i>	459

## LETTERS TO NATURE

New map of the optical polarisation of galaxy M82— <i>R. G. Bingham, D. McMullan, W. S. Pallister, C. White, D. J. Axon and S. M. Scarrott</i>	463
Variations of the infrared polarisation of VY Canis Majoris— <i>T. Maihara, K. Noguchi, M. Oishi, H. Okuda and S. Sato</i>	465
Fe XIII line in R Aquarii— <i>H. Zirin</i>	466
Pulsars and magnetic monopoles— <i>G. Kalman and D. ter Haar</i>	467
No anisotropy in angular diameter-redshift relationship— <i>A. Evans and D. Hart</i>	468
Present trends in the Earth's magnetic field— <i>J. M. Haxwood and S. R. C. Malin</i>	469
Possible late Precambrian subduction zone in South West Africa— <i>B. R. Watters</i>	471
A novel beryllsilicate phase containing 3-coordinate beryllium ( $\text{Rb}_2\text{Be}_2\text{Si}_2\text{O}_7$ )— <i>R. A. Howie and A. R. West</i>	473
Coccolith blooms in the Kimmeridge Clay and origin of North Sea Oil— <i>R. W. Gallois</i>	473
Dichotic verbal transformations and evidence of separate processors for identical stimuli— <i>R. M. Warren and J. M. Ackloff</i>	475
Correspondence between sharp tuning and two-tone inhibition in primary auditory neurones— <i>D. Robertson</i>	477
The Red Sea coral <i>Stylophora pistillata</i> is an <i>r</i> strategist— <i>Y. Loya</i>	478
Cell differentiation by 3',5'-cyclic AMP in a lower plant— <i>A. K. Handa and M. M. John</i>	480
Adenylate cyclase activity and steroidogenesis in phenotypic revertants of an ACTH-insensitive adrenal tumour cell line— <i>B. P. Schummei</i>	482
Inhibitory action of noradrenaline and cyclic AMP in explants of rat cerebellum— <i>B. H. Gahwiler</i>	483
Allergic sensitisation of human lung fragments prevented by saturation of IgE binding sites— <i>R. C. Godfrey and C. F. Gadidge</i>	484
Suppression of bacterially-induced hypersensitive reaction and phytoalexin accumulation in bean by phaseotoxin— <i>S. S. Patil and S. S. Gnanamanickam</i>	486
Collaboration between <i>in vivo</i> responses to LD and SD antigens of major histocompatibility complex— <i>H. W. Sollinger and F. H. Bach</i>	487
Association of high affinity stereospecific binding of $^3\text{H}$ -propranolol to cerebral membranes with $\beta$ adrenoceptors— <i>S. R. Naholski</i>	488
Synaptic transmission reversibly conditioned by single-gene mutation in <i>Drosophila melanogaster</i> — <i>K. Ikeda, S. Ozawa and S. Hagiwara</i>	489
$\text{Ca}^{2+}$ influx across the excitable membrane of behavioural mutants of <i>Paramecium</i> — <i>J. L. Browning, D. L. Nelson and H. G. Hansma</i>	491
Synthesis of ATP coupled with action of membrane protonic pumps at the octane-water interface— <i>L. S. Yaguzhinsky, L. I. Boguslavsky, A. G. Volkov and A. B. Rakhmanova</i>	494

## Guide to authors

● Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.

● Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).

● 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the *Système International*. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible,  $\exp(a)$  is preferred to  $e^a$  if  $a$  is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

• References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript. All artwork should be marked with the author's name. Line drawings should preferably be in Indian ink on heavy cartridge paper, although other materials are acceptable: thin, shiny, folded, torn or heavily handled material should be avoided. Matt rather than glossy photographs are preferred. Figures are usually reduced to one column width. The originals should be about as wide as a page of *Nature*. Figures, particularly maps, should contain nothing but essential material. It is preferred that the original be unlabelled, but with a copy containing lettering. Labelling on photographs should if possible be avoided entirely. We are always glad to see artwork for possible use on the cover, whether or not it is associated with a manuscript, but cannot guarantee the return of material.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

A fuller guide appeared in *Nature* (246, 238; 1973).

Antiviral, immunosuppressive and antitumour effects of Ribavirin—C. W. Potter, J. P. Phair, L. Vodnелиch, R. Fenton and R. Jennings	496
Relationship between the oncornavirus gene product gp70 and a major protein secretion of the mouse genital tract—B. C. Del Villano and R. A. Lerner	497
Isolation of nucleic acid-binding protein: stimulation of reverse transcriptase-catalysed DNA synthesis—P. P. Hung and S. G. Lee	499
Eukaryotic DNA replication complex—V. M. Genta, D. G. Kaufman, W. K. Kaufmann and B. I. Gerwin	502
Evidence for defined lengths of DNA replication units in 'satellite' DNA from <i>D. ordii</i> —T. A. Hori and K. G. Lark	504
Low temperature specific heat anomalies in melanins and tumour melanosomes—U. Mizutani, T. B. Massalski, J. E. McGinness and P. M. Cory	505
<sup>3</sup> H-concanavalin A binding of X-irradiated human fibroblasts—G. J. Koteles, T. Kubasova and L. Varga	507
Detection of bound ferulic acid in cell walls of the Gramineae by ultraviolet fluorescence microscopy—P. J. Harris and R. D. Hartley	508
Corrigenda	510

## ARTICLES

Hazards of plutonium with special reference to the skeleton— <i>F. W. Spiers and J. Vaughan</i>	531
Quantitative assessment of carcinogenic risks associated with 'hot particles'— <i>W. V. Mayneord and R. H. Clarke</i>	535
Aspects of the dosimetry of plutonium in bone— <i>M. C. Thorne</i>	539
Neutralised colliding beam torus— <i>R. M. Kulsrud and D. L. Jassby</i>	541

## LETTERS TO NATURE

Anti-correlated hard and soft X-ray intensity variations of the black-hole candidates Cyg X-1 and A0620-00— <i>M. J. Coe, A. R. Engel and J. J. Quenby</i>	544
X-ray transient source at high galactic latitude and suggested extragalactic identification— <i>M. J. Ricketts, B. A. Cooke and K. A. Pounds</i>	546
Mass determination for the X-ray binary system Vela X-1— <i>J. A. van Paradijs, G. Hammerschlag-Hensbeige, E. P. J. van den Heuvel, R. J. Takens, E. J. Zuiderwijk and C. De Loore</i>	547
Implications from the absence of a <sup>41</sup> K anomaly in an Allende inclusion— <i>F. Begemann and W. Stegmann</i>	549
Devonian palaeogeography of the Orcadian Basin and the Great Glen Fault— <i>R. N. Donovan, R. Archer, P. Turner and D. H. Tarling</i>	550
Kinetic processes and thermal history of slowly cooling solids— <i>M. H. Dodson</i>	552
Thermal conductivity of allotropic modifications of ice— <i>R. G. Ross, P. Andersson and G. Backstrom</i>	553
Intensity effects in the electrochemical photolysis of water at the TiO <sub>2</sub> electrode— <i>J. H. Carey and B. G. Oliver</i>	554
Effect of nitrogen-containing plasmas on stability, NO formation and sooting of flames— <i>J. C. Hillard and F. J. Weinberg</i>	556
The pace of life— <i>M. H. Bornstein and H. G. Bornstein</i>	557
Mortality and the 1974 fuel crisis— <i>R. E. Waller and P. J. Lawther</i>	559
Reply— <i>M. G. Maimot, S. M. Brown, S. T. Sacks and L. W. Kwok</i>	560
Wild mynahs mimic wild primates— <i>R. R. Teraza</i>	561
Wild birds detect quinine on artificial Batesian models— <i>E. C. Terhune</i>	561
Aggregation response of nymphs to pheromone(s) produced by males of the tick <i>Amblyomma hebraeum</i> (Koch)— <i>Y. Rechav, G. B. Whitehead and M. M. Knight</i>	563
Position-dependent development of tobacco meristems— <i>C. N. McDaniel and F. C. Hsu</i>	564
Unique Golgi apparatus and vesicle formation in a red alga— <i>R. Wetherbee and J. A. West</i>	566
Possible regeneration of $\gamma$ -aminobutyric acid-containing fibres into irides transplanted into the central nervous system— <i>P. C. Emson, A. Björklund and U. Stenevi</i>	567
Absence of transient tritanopia after adaptation to very intense yellow light— <i>J. D. Mollon and P. G. Polden</i>	570
Restoration of sensitivity of cultured hepatoma cells to cyclic nucleotides shows permissive effect of dexamethasone— <i>D. K. Ganner</i>	572
Role of serum in protease-induced stimulation of 3T3 cell division past the monolayer stage— <i>K. D. Noonan</i>	573
Specificity and reversibility of interferon ganglioside interaction— <i>F. Besancon, H. Ankel and S. Basu</i>	576
Thrombin-sensitive surface protein of cultured chick embryo cells— <i>N. N. H. Teng and L. B. Chen</i>	578
New structural characteristic of the large glycopeptides from transformed cells— <i>S. Ogata, T. Muramatsu and A. Kobata</i>	580

### Guide to authors

● Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.

● Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).

● 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

**Manuscripts** may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the *Système International*. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible,  $\exp(a)$  is preferred to  $e^a$  if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

● **References** are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

**Guide to authors**

● Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.

● Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).

● 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

**Manuscripts** may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the *Système International*. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, exp (a) is preferred to e<sup>a</sup> if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

**References** are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

**Artwork** should be sent with the manuscript. All artwork should be marked with the author's name. Line drawings should preferably be in Indian ink on heavy cartridge paper, although other materials are acceptable: thin, shiny, folded, torn or heavily handled material should be avoided. Matt rather than glossy photographs are preferred. Figures are usually reduced to one column width. The originals should be about as wide as a page of *Nature*. Figures, particularly maps, should contain nothing but essential material. It is preferred that the original be unlabelled, but with a copy containing lettering. Labelling on photographs should if possible be avoided entirely. We are always glad to see artwork for possible use on the cover, whether or not it is associated with a manuscript, but cannot guarantee the return of material.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

A fuller guide appeared in *Nature* (246, 238; 1973).

Effect of temperature and pressure on polymerisation equilibrium of neuronal microtubules—Y. Engelborghs, K. A. H. Heremans, L. C. M. De Maeyer and J. Hoebeke	686
Androgen-sensitive midbrain sites and visual attention in chicks—C. C. Meyer, D. M. Parker and E. A. Salzen	689
Interspecific variation in products of animal mitochondrial protein synthesis—A. J. Jeffreys and I. W. Craig	690
Ribosome metabolism in temperature-sensitive mutant of BHK cells—A. Kumar, E. Bandman and W. T. Melvin	692
Magnitude and significance of NAD turnover in human cell line D98/AH2—M. Rechsteiner, D. Hillyard and B. M. Olivera	695
Translation of oncogenic virus RNA in <i>Xenopus laevis</i> oocytes—M. Salden, F. Asselbergs and H. Bloemendal	696
Homology of myosin DTNB light chain with alkali light chains, troponin C and parvalbumin—J. H. Collins	699

## Snooping with a CRT

A nurse with access to health records by means of a computer terminal types in her boy-friend's name and finds his medical history. It is not all she would have hoped for. She breaks it off with him.

A defendant in a well publicised civil case has an alibi which the court accepts. A credit card company employee, out of curiosity, calls up his file and finds that his alibi is not borne out by the list of his transactions.

A hotel booking clerk uses a computer terminal to check on a putative guest and finds that a year ago, in a different hotel, he left without paying for his room. The guest, immediately on discovering his oversight, had paid the bill by post. But this correction never got into the computer. He is told the hotel is full.

THESE are three of the diverse ways in which computers can facilitate information-collecting in somewhat murky circumstances. The Home Office has recently published a White Paper on Computers and Privacy (Cmd 6353, 28p), and with it a summary of an interdepartmental working party's review of computer usage in the public sector, with particular reference to safeguards to protect privacy and confidentiality. Back in 1972 Sir Kenneth Younger's Committee on Privacy reported that, although there was no evidence that the private sector was using computers to threaten privacy, there was need for vigilance, in the form of an independent body to review the gathering and processing of personal information. The Younger Committee also gave the government gratuitous advice that such an independent body could, in addition, study the public sector. This White Paper advances the cause of a Data Protection Authority to oversee the handling of personal information. It also gives some reassurance that, in as far as the evidence exists, the use of computers to impinge on people's private lives is not on the increase.

Privacy is a misnomer. We are really talking of the use of personal information for purposes other than that for which it was supplied or collected, and the use of inaccurate or incomplete data where the person reported on has no chance to challenge the accuracy or completeness.

Computers is also a misnomer, so to say. Computers have not, up to the present, created new opportunities for misuse of information; they have simply made

possible quicker and larger operations, allowing instant decisions to be made. Newspapers, or gossip in the staff canteen, still have the potential for much more damaging intrusions into the life of the individual than do computers. Nonetheless the computer, with its 1984 image, attracts a lot of the fire, and is often credited with monitoring skills that it does not possess.

The average reader of *Nature* would, however, probably settle for more automation in dealing with public and private enterprise. The tedium of paying separate bills for mortgage, licences, utilities, insurance—of having different numbers for health services, tax authorities, passport, bank, telephone, credit cards—often niggles; roll on rationalisation. But one third of the population of the UK regards it as an invasion of privacy even to have publicly available lists of names and addresses such as electoral lists or telephone directories. With such extremes of opinion, is there any hope that a statutory agency such as the White Paper envisages can satisfy everyone that information is not being misused?

The Younger Committee put forward ten principles for the handling of personal information in computers, including one that "there should be arrangements whereby the subject could be told about the information held concerning him". The White Paper proposes more—"the subject should also be able to find out what has been done with the information, and to whom it has been given". In a society of technocrats, we would all receive a weekly listing of what was held in data banks about us, and by whom that information had been used; the big advantage of storing information in computers, of course, is that all usage can be logged. If we found someone had been nosing around without authority, we would call our lawyer. But that one third of the nation which does not even want names and addresses listed probably has little idea of what to do if supplied with computer print-outs. It certainly is not in the habit of consulting lawyers.

Here, then, is a real job for the Data Protection Authority—to make sure not only that everyone knows what the information they have provided is being used for, but also that ways are devised for fighting misuse at the level of the individual. Many of the biggest threats to the individual, after all, do not come from the computer at all. But perhaps an imaginatively appointed Data Protection Authority, not stuffed with "the good and the great", might lead the way towards broader initiatives to look after those in greatest danger of being trampled on.

## Can Europe clean itself up?

*Despite the rhetoric that bursts forth when principles of European Economic Community action are outlined, environment policy remains something of a backward region. Progress towards common action at Community level has been tardy, not through a lack of ideas but a paucity of decisions. Paul Cheeseright reports.*

IN THE EEC, environment is a policy looking for an executor. Yet opinion polls would suggest that a more vigorous approach by the Community's decision-making arm, the Council of Ministers, would not be lacking in some sort of popular acclaim. Nearly 10,000 people questioned throughout the Community in the middle of last year were asked to list the most important problems facing the Community. Second on the list of five major concerns came nature conservancy, and most of the interviewees favoured European action to deal with all of the problems.

In fact, a vast amount of work into the problems and techniques of environmental control is proceeding within the Community. The great problem, however, is that most of it is uncoordinated, and at Brussels there is simply inadequate information to gain a coherent picture. For this reason, it was agreed towards the end of last year that the European Commission, the ideas centre and civil service section of the Community, should pull together an inventory of sources of information on the environment. The data would be supplied by the nine member states and include independent research exercises. The information supplied would be processed in such a way as to be compatible with similar groundwork being undertaken for the UN international reference system on the environment.

This measure extends the interchange of information that was begun in 1973 when the Community took its first halting steps towards harmonising national legislation on the environ-

ment. When one state desires to take action in an area where the Commission has not presented proposals, the measure can only come into effect six months after the Commission has been informed and only if the Commission has presented no proposals to the Council. Under an agreement of March 1973, the Commission is in any case informed of draft laws, regulations or administrative provisions. In the first two years after the agreement it was informed by the member states of 22 laws or regulations, 67 draft provisions and six international agreements, the greater part coming from Denmark, France and Germany.

The existence of such mechanisms acts as a check on the use of environmental policy in a purely chauvinistic sense, and is an acceptance of the principle that environmental policy applied in any determined fashion is a nonsense when conceived in a purely national framework. Indeed, one of the lessons of the international conference at Stockholm in June 1972 was that in the absence of any international organisation to supervise the improvement of the European environment, only the Community can execute a policy that transcends national frontiers. Yet the Community has only limited powers, and over the next decade it seems likely that any steps taken will work towards the mitigation of problems rather than their cure or outright prevention. This is not to say that water will not become purer or the air cleaner, but it is to say that there are certain forces at work within Europe that will not be pushed aside.

Among them is the demographic trend which even before 1970 had shown that 30% of the population of France, Germany, Italy and the Benelux countries was concentrated in 9% of the available land area. Further, in the area of greatest population concentration, the birth rate was found to be more than double that of the outlying regions. The result of this trend could be to entrench the so-called Golden Triangle, the industrial area that extends from the Midlands of England to the Gulf of Genoa. Any environmental policy is inevitably linked to balanced development. But this is not taking place, and, indeed, the Community's agricultural policy is actually encouraging people off the land into the industrial conurbations.

Under the liberal capitalist economic systems of the Nine, new industries are usually attracted to the main market areas, thus strengthening the tendencies towards pollution that have been created by a century's unplanned search for industrial prosperity. In the strictest terms, then, a successful Community environment policy demands some control over the disposition of economic activity. But there is no power to create such a system of control, nor much evidence of any desire to create it. It would involve the emergence of a supranational state which, while it might be the aim of the European integrationists, is scarcely a realistic political concept for the time being. Community environment policy is likely to remain something of a patchwork while the politicians strive to come to terms with what the Community's Altiero Spinelli once called "a spectrum of complex interdisciplinary problems, whose impact, interconnection and consequences are frequently not completely known as yet." There is the additional problem that the environment as such is not mentioned in the Treaty of Rome and that, freed from the legal requirements of common action, the member states' movements on an integrated policy will be a direct reflection of their somewhat haphazard desire to move closer together politically.

It is against this background that the Community has been formulating and enacting a limited environment policy. The Community was a relative late-comer to the field. It was not until 1971 that the Commission established a special unit to deal with policy, and it was only at the Community summit meeting of October 1972 that their efforts received much political recognition. A detailed action programme was ordered for presentation in the middle of 1973. This programme was adopted later and ran until the end of 1975. Now a further programme to cover the next five years, with revision after

2½ years, is under consideration.

The main thrust of the Community's first programme covered three broad areas. In the first place the aim was to prevent or reduce pollution; the second aim was to improve the environment generally and then, finally, to push forward Community involvement in the framework of international action on the environment. Within these general areas, the Community adopted the principle that "the polluter pays". This may turn out to be something of a misnomer, for the real fact is that the consumer pays. Where factories or agencies take steps to minimise their pollution of the environment, it is inevitable that this will be reflected in the prices charged for the products created. In addition, governments are using taxpayers' money to aid companies introducing anti-pollutant measures. The Community has since the end of 1974 had a general rule as to the apportionment of costs and the role of the public sector in providing aids for anti-pollutant measures. But this measure is less concerned with safeguarding public money than preventing the companies of one country gaining a competitive advantage over those of another.

The Community has also adopted a set of rather obvious principles for the administration of environment policy. There are eight in all, aimed above all at the co-ordination of national programmes. The use of natural resources which damage the ecological balance should be avoided, environmental damage should be prevented rather than corrected afterwards, technical progress must include efforts to protect the environment, the polluter should pay, the environment will be taken into consideration at an early stage of technical planning, activities in one country should not damage another and there should be nothing to impede the operation of the common market. The principles are banal, but significant in the European context mainly because they had not been enunciated before.

At the Community level, numerous research programmes have been set moving and plans for a European Foundation for the Improvement of Living and Working Conditions have been laid so that the Foundation should start working early this year. The Council has also adopted a resolution on the desirable quality of surface waters required for drinking and a recommendation on the storage and treatment of waste oil, and has adopted the Paris Convention for the prevention of marine pollution from land-based sources. At the end of 1975, the Council agreed that the Commission should represent the Community in international negotiations aimed at providing a basis on which it will be

possible to keep the Mediterranean cleared of pollution emanating from the land. In this case, the Commission's mandate is an extension of the agreement that was reached at the Paris Convention, which covered the North-East Atlantic. These examples give a flavour of the breadth of the work that is being undertaken at the Community level, although it can be argued cogently that the effort is minimal when related to the scale of the problems to be solved and the power of the Community when acting in a united fashion to solve them.

---

**6 Given a problem it is possible to suggest a scientific counteraction. But Community problems are not dealt with according to such simple terms 9**

---

But this really points up the difficulties that the Community is facing. Given a problem it is possible to suggest a scientific counteraction. But Community problems are not dealt with according to such simple terms. In the first place, there might be, and often is, argument about the scientific response to the problems because the geographical nature of the Community is so varied. In the second place, any scientific response to a problem has to be consistent with the overriding economic aims of the Community. Of course, the Community is concerned with economic growth, but the difficulty goes deeper than that into the existence of the common market. It is a dominant principle that the common market should not be endangered, that there should be free traffic in goods and that no company or country should have an advantage over another, created by the Community rules.

Two incidents in recent months provide evidence of the dilemma created by these circumstances in the Community. One instance remains unsolved. The other has been widened to embrace a compromise that might embrace the environmental end, while taking into account the nationally-based scientific and economic means.

The first relates to the content of lead in petrol, a subject which the Community has broached but has never been able to follow through because of the opposing national attitudes and interests. At the beginning of the year the West German Government was due to introduce a new regime governing the extent of lead permitted. In introducing stricter measures in the interests of curbing air pollution, the Germans have pursued a policy that is further advanced than that of other Community states. On January 1, the Germans reduced the legal lead content in petrol to 0.15 grams per litre from

0.4 grams. Precisely because the German regulations will be stepping outside the commercially accepted norms, the Commission has received complaints from a group of German oil companies and a number of Dutch firms that, as they are unable to meet the 0.15 grams regulations, they are being forced out of the market. Therefore, the companies argue, the regulation is an infringement of the principle of the common market and free competition. The case remains unresolved.

The second instance concerns the emission of toxic waste into the aquatic environment. It was the subject of bitter dispute between Britain and the other eight members of the Community at a Council meeting in October. A compromise was reached in December. Broadly the eight members wanted discharge controls for pollutants like cadmium, mercury, organohalogenic, organophosphoric and organotitanic composites, and a list of others making up a so-called black list Britain, on the other hand, argued that there should be an observance of quality control objectives—in other words, there should be no control on discharge where it could be indicated that the discharge did not affect the immediate environment. The eight contended that unless there was a uniform emission standard there would be distortion of economic competition. The British rejoinder was that this was nonsense and that there should be recognition that geographic factors were different in the varied parts of the Community. Britain had short rivers, a long shoreline and not many factories on the rivers. The compromise finally agreed was that emission standards should be used but there could be exceptions where quality objectives may be used.

While the Community, it may be argued, lost a chance, because of British intransigence, to move forward into the area of positive controls, it came face to face with the fact that environmental policy will have to be flexible in the future. The conditions in the north of Scotland are not the same as those in Sicily. If fish are not given a chance to live in the Rhine, they are breeding more heavily in the Thames. But beyond this, the flexibility of the approach to aquatic pollution is probably more in keeping with the political realities of 1975-6.

In a general sense, the environmental lobby is not as strong as it was in 1972-3, except insofar as it can bring its power to bear on local issues of immediate importance. And even if it was, it would not necessarily make much difference. Environmental policy in the Community has less to do with science and more to do with politics and economics. □

# international news

Just four years ago, President Nixon signed into law a piece of legislation which has fundamentally changed government support of biomedical research in the United States. Called the National Cancer Act, the legislation was designed, in Mr Nixon's words, to launch "a great crusade against cancer". The crusade has always been controversial, causing deep divisions within the biomedical research community about how it should be managed. But it has recently come in for some fresh criticism which bears especially close watching. In fact, the indications are that a major political debate about the structure and scope of the cancer research programme is beginning to take shape.

Even before Mr Nixon put his signature to the National Cancer Act, the measure was controversial. The chief bone of contention in the early days was the justifiable resistance within the scientific community to the notion that cancer research could be managed like an Apollo-style effort to land men on the Moon. Though concerns over the NASA-like approach persist, frequently finding expression in attacks on the huge amount of money being spent on efforts to track down human cancer viruses, criticisms of the cancer research crusade have recently coalesced around two arguments, both of which have been raised in debates in Congress in the past few weeks. The first is the argument that rapid increases in funds for cancer research have siphoned money from other, equally deserving, research programmes. And the second is the contention that the cancer crusade has concentrated on an elusive search for cures and treatments at the expense of prevention—in short, environmental causes of cancer have been relatively neglected.

The first complaint is by no means novel. In fact it was raised three years ago when Mr Nixon cut back research budgets across the board but spared the politically sensitive cancer programme from the axe. The matter took on a new dimension last September, however, when a group of Senators, led by Gaylord Nelson of Wisconsin and Alan Cranston of California, proposed an amendment to a budget bill which would have pared down the budget for the National Cancer Institute and redistributed some of the savings to other institutes of the National Institutes of Health (NIH).

The amendment was soundly defeated, but the issue of research priorities got a good airing on the Senate floor.

Armed with a sheaf of statistics and with letters of support from former NIH directors and top government health officials, Nelson and Cranston provided details of how the budgets have grown for cancer research and, to a lesser extent heart research (which was aided by the National Heart, Lung and Blood Act of 1972), while budgets

## Cancer controversy recommences

by Colin Norman, Washington

for other NIH institutes have languished. Between 1970 and 1975, the budget for the National Cancer Institute (NCI) rose by 280%, from \$182 million to \$669 million, and the budget for the National Heart and Lung Institute (NHLI) increased from \$159 million to \$303 million, while spending on all the other 11 institutes rose by only about 20%, from \$750 to \$908 million. In constant dollar terms, NCI's budget rose by 186%, NHLI's increased by 52%, while the rest of NIH suffered a 13% drop in funds.

Although few Senators were willing to vote for a redistribution of funds to less politically favoured research programmes, the matter of biomedical research priorities is now under intense scrutiny by a top-level Presidential commission which is examining NIH's research policies. Established last year by a bill sponsored by Senator Edward Kennedy, the commission is due to issue a report by April 30, and its findings are likely to spark a fundamental re-examination of biomedical research policies and priorities.

The second major complaint raised recently about the cancer crusade is that the effort is devoting insufficient attention to finding ways to prevent, rather than to treat or cure, cancers. The impetus for such complaints is generated by two factors. The first is the growing realisation that the majority of human cancers may be linked to environmental factors, such as carcinogens encountered in the work place and in the general environment (including cigarette smoke). The second is the fact that in spite of massive expenditures on cancer research, survival rates for people suffering from

many of the leading cancer killers have improved little since the 1950s.

Thus, Russell Train, the head of the Environmental Protection Agency, pointed out in a recent speech that as many as 60–90% of human cancers can be traced to environmental causes, and he suggested that "we may be approaching the whole question of human health from the wrong side . . . an ounce of prevention may well be worth a pound of cure".

Similar sentiments were expressed more bluntly last year by a sub-committee of the National Cancer Advisory Board, NCI's top advisory body. The sub-committee, which was chaired by Dr Philippe Shubik of the University of Nebraska, expressed its "sense of general astonishment" that the cancer programme "does not appear to have accorded an adequate priority nor sense of urgency to the field of environmental carcinogenesis". The sub-committee's report went on to recommend that more money be put into chemical carcinogenesis (it estimated that less than 10% of NCI's budget is now spent on such studies) and it suggested that if necessary some money should be reprogrammed from other fields, such as tumour virology.

NCI officials have generally countered that they are spending much more than 10% of their budget on environmental carcinogenesis, and that if good research proposals in that field come along, they will certainly be funded. Nevertheless, complaints about lack of attention to environmental carcinogenesis have percolated through to Capitol Hill, and last month Congress approved an appropriations bill for NIH (which has since been vetoed by President Ford), which contained \$3 million to establish a research programme on job-related cancers.

With discoveries of new occupational and environmental carcinogens—such as the link between vinyl chloride gas and liver cancer in plastics workers—continuing to flood in, the death rate from cancer continuing to increase (it rose dramatically in the first six months of 1975 in the US, but the increase may be a statistical quirk), and the cancer programme continuing to occupy a politically favoured position in the federal budget, it seems inevitable that there will be a renewed political debate about the structure and scope of the cancer programme this year. □

DELEGATES from the contracting parties to the London Dumping Convention 1972, along with observers from other countries and interested international organisations, met for the first time last month in London to choose an appropriate organisation to undertake its secretariat duties and to begin preparations for its first substantive meeting later this year.

The world-wide Convention—its full title is the Convention on the Prevention of Marine Pollution by Dumping of Wastes and Other Matter, London 1972—has been signed by 54 states, 22 of which have ratified it. The Convention prohibits the dumping at sea of certain dangerous substances, including mercury and cadmium and their compounds, organohalogen compounds and highly radioactive materials, and subjects the dumping of a large number of other substances to stringent control by the issue of specific permits by national authorities.

The conference agreed to a joint proposal from Britain and Mexico that the secretariat's work should be given to the Inter-Governmental Maritime Consultative Organisation (IMCO), the London-based UN agency with over 90 members which has until now administered conventions regarding marine pollution from ships and operated in the fields of marine safety and navigation.

The conference set up a working committee to examine the plan, and also agreed that the first substantive meeting of contracting parties to the Convention should be held in September.

- The enforcement from the beginning of January of further provisions of the Control of Pollution Act 1974, which covers waste disposal and reclamation, noise, water and air pollution, has coincided with the Department of the Environment's latest survey revealing a further slight fall in the extent to which the UK's rivers and canals are polluted.

A total of 840 miles of river and canal is now classed as "grossly polluted", a reduction of 46 miles. The improvement has increased marginally the lengths of river classed as "poor quality requiring urgent improvement", but at the other extreme an extra 160 miles have been added to the lengths considered free from pollution.

The survey is based on tests carried out in 1973. The improvement on the previous survey in 1972—the first was made in 1970—was less marked in tidal rivers and canals than in non-tidal rivers. And altogether a total of 182 miles was downgraded.

- The reports of three separate committees examining lead levels in food were published last month when the Working Party on the Monitoring of Foodstuffs for Heavy Metals carried in its fifth report (*Survey of Lead in Food: First Supplementary Report*) two appendices containing the advice of the Food Additives and Contaminants Committee and of the

## Around Britain

toxicity sub-committee of the Committee on Medical Aspects of Chemicals in Food and the Environment.

The Working Party, whose second report, in 1972, was also a survey of lead in food, concluded that the amounts of lead in the average diet in the UK had not increased since then, and that the mean lead concentration in canned infant foods had significantly decreased. The toxicity sub-committee, which advises the Food Additives and Contaminants Committee and various government departments on the toxicological aspects of the use or presence of additives and pollutants in food and the environment, considered that the present intake of lead from food in the UK was unlikely to constitute a hazard to the health of the general population.

The Working Party's surveys, involving the analysis of some 6,000 samples of foodstuffs and nearly 12,000 samples of drinking water, showed that the average consumer's lead intake was less than half the 'provisional tolerable weekly intake' of 3 mg for adults, published by the FAO/WHO.

But the Food Additives and Contaminants Committee, although endorsing the underlying view, recommended reductions in the maximum permitted amounts of lead in food in its separately published *Review of the Lead in Food Regulations*. Margins of safety were not as great as could be desired, the

committee argued. It wanted ministers to enforce a limit of one part per million for most foods, a lower limit for baby foods, an end to the exemption from all limits of fish in which lead occurs naturally, and extra efforts to cut the amounts of lead in tinned foods.

- Just a couple of weeks after the announcement that Lord Beswick would head the new publicly owned corporation British Aerospace when it is formed—an appointment that attracted some Opposition criticism because he has not held an executive position of any sort in industry—the Labour Government named the board members of the new British National Oil Corporation (BNOC) whose first task will be to organise the structure of the state oil undertaking. And on the list so far is not a single senior oil industry management executive.

Indeed, the only man with any remotely practical experience in the area seems to be Mr Denis Rooke, chairman-designate of the British Gas Corporation. But his appointment, like that of the chief executive of the Shetland Island Council, drew speculation about conflicts of interest as well as about BNOC's possible influence over British Gas. And the inclusion of Lord Balogh as deputy chairman, a part-time post, has raised questions about BNOC's independence from government interference, because although he has retired as Minister of State at the Department of Energy (headed by Mr Anthony Wedgwood Benn), Lord Balogh remains Mr Benn's special adviser.

The chairman of the board, which also includes a lawyer, a trade union leader and several civil servants, is Lord Kearton, formerly head of Courtaulds.

- Dr Walter Marshall, the Director of Harwell, the Atomic Energy Research Establishment, is relinquishing his position (though not, apparently, his office) there to become deputy chairman of the UK Atomic Energy Authority (UKAEA) on Mr Frank Doggart's retirement. He will retain his other major post, that of chief scientific adviser to the Department of Energy, except when it comes to nuclear matters, which are the province of the UKAEA chairman, Sir John Hill.

The move, announced by Mr Benn, marks a large promotion. Dr Marshall was, at 43, the most junior member of the UKAEA Board; he now has responsibility for scientific and technical policy throughout the organisation. Dr Lewis Roberts will take his place as director of Harwell.

AS THE Council for Mutual Assistance (Comecon) countries considered the end of their 1971-75 Five-year Plans and formulated their plans for the coming five years, a whole series of meetings, conferences and discussions were held of the Standing Comecon Commissions. Plans have been put forward on such diverse matters as the unification of standards for industrial production, the approval of new drugs to be used in the treatment of malignant tumours, the division of labour between the participating countries in the manufacture of electronic components, and specialisation and co-operation in the manufacture of instruments for the artificial insemination of cattle.

For the first time, the new plans will include the construction of joint industrial projects by a number of member countries. And the non-European members of Comecon are not forgotten. Within the framework of the existing scheme for the integration of information systems, Czechoslovakia and Hungary are to provide information systems for Cuba, and the Soviet Union will provide Cuba and Mongolia with industrial, agricultural, and transport equipment in return for basic exports and raw materials.

● The new Polish five-year plan, as laid down by the Seventh Congress of the Polish United Workers' Party which met in Warsaw from December 8-12, envisages a considerable expansion of investment in science. This is despite the fact that the growth of the Polish economy in the five years of the Gierek regime has been facilitated by foreign borrowings which, in bringing

demands for interest payments, will make higher prices and food shortages likely over the next five years.

## Comecon diary

from Vera Rich, London

Expenditure on both science and technology is put at 200,000 million zloty, after 115,000 million in the previous five years. Special emphasis is to be placed on research into the more efficient use of fuels, raw materials and water resources, improving the technology of the coal and copper industries, the introduction of aluminium production from native ores and the production of new materials for the electronics industry. The application of science to agriculture, public and occupational health and child care are also mentioned.

According to Sylwester Kaliski, the Minister of Science, Higher Education and Technology, the plans will be im-

plemented through a new scheme which, with cooperation between scientists and administrators, will lay the foundation of a "strategy for scientific research and technical advance, a plan composed of government programmes, departmental problems and basic research". This, he said, would unify the whole activity of research and its practical implementations in Poland.

The Polish Academy of Sciences is to play an important role in the research part of this programme, and it is introduced also to involve the universities.

● In the German Democratic Republic's economic plan for 1976, which (if successful) will result in a 5.3% increase in the national income, a 6% increase in the production of industrial goods and an improvement in labour productivity of 5.5%, the plan for science and technology envisages more than 160 specific tasks to be fulfilled on time and to a high standard. The "tasks" cover a wide range of applied science, from improved fuel economy in power stations to rationalisation of the washing-powder industry.

The attainment, or otherwise, of the proposed targets may itself be somewhat difficult to evaluate, however. According to the East Berlin Central Statistics Board, a number of enterprises in the GDR have been "interpreting in their own special way" their economic results for 1975, so that in many cases the figures submitted make the drawing of any sound economic conclusions problematic. The board urges exact calculation, rather than "interpretation", of the figures.

## Indian states attack population growth

from Our Correspondent, Jullundur

AFTER more than two decades and the expenditure of thousands of millions of rupees, India's family planning programme has achieved only limited success. But Draconian measures proposed by two state governments may well change all that through a revamped and much more severe stick-and-carrot policy to encourage sterilisation.

Taken up officially in 1952, the Indian birth control programme started off modestly, but only received its first big push after the publication of the 1961 census data, which showed a higher-than-expected rate of population growth. The programme has nevertheless made only slow progress. According to official figures, the present birth and death rates are 36.6 and 16.9 per thousand respectively. Due to improvement in health services, the

death rate has fallen and is expected to go down even further. But the slow decline of the birth rate can be attributed to a number of factors. Paucity of funds, inadequate communications and lack of official enthusiasm at lower levels have proved obstructive; but poverty, malnutrition, ignorance, superstition and illiteracy are the more formidable hurdles. There have been suggestions that new families be allowed to have no more than two children. But so far the government has steered clear of introducing compulsion into the programme, even though the population increases each year by an amount equivalent to the population of the whole of Australia.

The state governments of Haryana and Punjab, however, have decided on steps which could spell the beginning of a new trend. The Haryana government has announced a series of measures to promote smaller, two-children families by means of incentives and disincentives. The state has set itself a target of reducing its net

rate of population growth to zero before 1985.

The incentives include cash prizes worth 100,000, 75,000 and 50,000 rupees, which will be awarded each year to three districts in the state which capture top spots in family planning performance over and above their allotted targets. Factories in the state, where all 'eligible' workers accept sterilisations after two children, will qualify for benefits from a 'Labour Welfare Fund', and the best village-level governing bodies in each district will also be eligible for cash bonuses. All children of 'eligible' government employees will be entitled to reimbursements of medical expenses up to the age of 5; thereafter only two of them will be given this facility. Employees who already have more than two children will only receive medical reimbursements if they are sterilised within a year of the date of enforcement of these decisions.

The disincentives are aimed primarily at government employees with

more than two children who fall into the category of 'eligible' couples. Unless they get themselves sterilised within 12 months, they will not be allotted government accommodation, or, if they are already in possession of government accommodation, they will be charged standard rent; they will not be allowed any house-building advance, or loans for buying wheat or vehicles; and on being transferred, they will receive travelling allowances only for two of their children. New recruits into Haryana government service will have to undertake not to produce more than two children. A third child will render them liable to dismissal.

Days before the Haryana government decisions, the Punjab government had announced similar measures to curb the rate of population growth in that state. Among other things, women employees in Punjab would no longer be provided the facility of maternity leave and other related benefits beyond the second child. □

## Commission foresees 200-mile limit

THE European Commission has recently disclosed details of proposals regarding European fishing policy, grasping in the process the nettle that the problem of 200-mile fishing limits represents.

The plans, which now require a decision from the nine member governments, envisage a time when 200-mile fishing limits are approved—most likely at a forthcoming session of the UN Law of the Sea Conference. Member governments are enjoined to formulate a common position on the issue.

The Commission emphasises the need for conservation of fish resources in its proposals, and this would probably involve setting catch quotas. The inland waters of each of the nine member states should, it says, be opened to fishermen from other member states

(this is due to happen after 1982), and argues that special arrangements will have to be made to protect inshore fishermen and preserve fish stocks when limits are extended to 200 miles.

Quotas would have to be negotiated with non-member countries like Spain and Norway, the Commission says, and access terms for Community fishermen in their waters would also have to be agreed.

In Norway itself, meanwhile, the minister in charge of questions relating to the law of the sea, Mr Jens Evensen, has spoken about the sort of agreements he foresees regarding conservation and quotas. He was indicating new guidelines for Norway's negotiations with 15 countries about the establishment of its proposed 200-mile economic zone. The total catch, he said, should be allotted to the various countries with a clear preference for the coastal states. And he described the EEC fisheries policies as a "heavy burden for Europe". □

OPEN season on the Food and Drug Administration (FDA) is, as usual, in full swing; cannon to right of them, cannon to left of them, volley and thunder, in the "health food" magazines, in *Science*, where the anti-everything editorial staff have long used FDA as a favourite target, and even in *Nature*.

A new report on cyclamates says that "a blue-ribbon scientific panel" tentatively concluded on December 10 (with one dissident) that more than 20 new studies with animals failed to show cancer, birth defects or genetic damage. Now what happens? If cyclamates are put back in soft drinks, the Center for Lawyers in the Performing Arts will erupt in rage, aided by FDA's in-house consumerist, who will inject chick embryos with cyclamates. The embryos will die. Chickens, unlike dogs, are expendable. (But what dog ever laid a nice, fresh breakfast egg?) The FDA will be accused of collaborating and conniving with the pharmaceutical industry to put a poison in our food.

However, if cyclamates are not put back in soft drinks, the Toby Belch Society, or some other watchful guardian of the obese, will protest angrily. The FDA will be accused of plotting and conspiring with the sugar industry to keep a harmless sweetener from people who need it in reducing diets. The FDA must indeed feel grateful for the existence of cyclohexylamine, a metabolic product of cyclomates that may give the regulators a little breathing spell while it is further investigated. Few of the critics will bother to read the Federal

Food, Drug and Cosmetic Act, which gives very specific directives for evaluating applications for the use of food additives.

Some confusion in this general field undoubtedly arises from lack of understanding of the "GRAS"

## The policeman's lot

THOMAS H. JUKES

(generally recognised as safe) list. This list, which is currently being overhauled, includes about 670 substances recognised in 1958 as suitable for food, compiled from FDA food standards, from State regulations, and from lists of substances "known to have been used in food for some years without reported adverse effects." Long custom rather than scientific investigation led to the acceptance of most of these as (or in) foods. Undoubtedly, many of them would not "make it" if intro-

duced as "new" food additives. The FDA appears to be getting blamed for allowing bacon, containing mutagenic substances, to be sold. Just who got the idea of soaking meat in nitrates to preserve it is not clear, but the practice certainly antedates the FDA, and the present century. For that matter, the treatment of meat with smoke adds carcinogens to the diet, and this process must have originated in the caves of our remote ancestors.

The FDA points out that, for all food additives, new information casting doubt on safety will lead to "necessary measures provided for in the law to be undertaken to protect the public health." Actually, some additives, such as safrole, have been quietly dropped. There are no provisions, of course, for using new information of a positive nature, such as the increase in mean life span of mice, and the partial suppression of carcinogenicity of certain aromatic amines, both reported for the antioxidant butylated hydroxytoluene (BHT), whose name is enough to make it suspect, regardless of its properties.

Meanwhile, FDA is still ducking bullets on other issues, as described in *Nature* (November 20). Charges of "industry favouritism" by disgruntled employees make great headlines, and nothing is duller than a rebuttal. Industry, of course, says it is strait-jacketed by FDA. The pushers of the quack cancer remedy "Laetrile" say they are, too, as they lie a-basking in the sun, south of the border, down Mexico way. The policeman's lot is not a happy one.

# correspondence

## Higher education

SIR,—May I comment on two related articles on higher education which have appeared in recent issues of *Nature* (November 13 and 20)? The question of whether universities should be concerned with "education" or with professional "training" is raised in relation to the balance of faculties and the cost to the taxpayer.

In my view there is a need for two distinct types of higher educational institution. One of these, traditionally universities, should be principally concerned with scholarship and furthering the bounds of human knowledge, and with passing on the fruits of such knowledge and research, through teaching, to any who are sufficiently interested and wish to receive it. Examinations, if they are appropriate here at all, should not take the form of professional qualifications, but should rather be used for selecting academics to continue the work of the university.

The other type of institution should have the specific function of training for professional qualifications. Such an institution might be a polytechnic where the teaching should be geared to qualifying examinations for professional men expecting to practise in medicine, the law, sciences, engineering, business management or whatever. The teachers should have had some years of practical experience and they should constantly refresh that experience on a sabbatical principle or by periodical exchanges with practitioners. Research work should be aimed at practical application in response to the needs of industry, hospitals and so on.

Universities should be reduced in number and much reduced in size, but the balance of faculties should certainly be maintained. This would provide an environment for the broad education of relatively few who are academically inclined and who would be expected to achieve the highest standards of excellence in scholarship, imagination and innovation.

Polytechnics could afford to be more specialised and might benefit from it. In order that the trainees should not suffer from a lack of education in the broader sense, the polytechnics should allocate some course time to a variety of subjects for which the universities could send lecturers and set up

seminars. There would be no examinations in these extra-curricular subjects and a wide choice should be offered.

The courses offered by polytechnics should ensure that a sound basis of theory and practice is achieved, and the chartered professional bodies should have a considerable voice in the curricula and in the form and content of the qualifying examinations. In some professions where developments are rapid, it might be desirable to insist on further training and examination at intervals to ensure that high professional standards are maintained throughout a career.

Developments in the future along these lines might ensure better academic research, better professional standards, and give better value for the taxpayer's contribution to higher education.

Yours faithfully,

A. C. MASON

Wirral, Merseyside, UK

## The protein gap

SIR,—Man has always desired simple answers to the complex problems of the world; to reduce everything to a common denominator. Many have done this with regard to nutritional problems, claiming over the past twenty years that protein was the only answer. As Drs Waterlow and Payne point out in their article "The Protein Gap" (November 13), this is not true. Unfortunately they then fall into the same error by concluding "the protein gap is a myth and what really exists . . . is a food gap and an energy gap". The new simple answer for them is energy.

Protein-energy malnutrition, be it kwashiorkor or marasmus, has never been, except in the rarest of cases, a single nutrient deficiency disease. It has always involved the lack of vitamins and minerals as well as energy and/or protein and all the other factors required for good nutrition.

To talk only of energy and protein as the FAO/WHO report did, and as the authors do, is meaningless. To suggest merely that more of traditional diets is all that is needed is, in most cases, no solution to nutritional problems. Many of these diets were shown to be inadequate by early workers such as McCarrison and they continue to be shown so in current studies.

Nutrition deficiencies are encoun-

tered primarily in populations with a limited choice of foods. Adequacy is best assured through the use of a wide variety of foods having complementary patterns of nutrients, as has been pointed out by the US National Academy of Sciences. This means improving traditional dietary patterns.

Until man is willing to reckon with the complexity of the nutrition problem and to deal with it as such, he is doomed to repeat the errors of the past.

Yours faithfully,

WALTER J. BRAY

Department of Food Science,  
University of Reading, UK

## Human consumption

SIR,—The statistic of the Potato Marketing Board quoted in *Nature* (December 11, page 484), and quoted here in full,

"Contrary to the trends in all other countries in the European Economic Community the rate of movement into human consumption in Great Britain increased during the three previous seasons (and shows a provisional offtake for 1974/75 of 222 lb per head per annum)",

may suggest spud-deficiency to you, but it may imply an alarming increase of cannibalism to others.

Yours faithfully,

JOEL J. LLOYD

National Academy of Sciences,  
Washington, DC 20418

## Peace Prize

SIR,—Your leader (October 16) concerning the awarding of the Nobel Peace Prize must be the ultimate expression of English diplomacy. Tell me, what better example anywhere of peaceful struggle for freedom is there than Sakharov's? No one would have to lose any freedom themselves to satisfy his requests, and unlike some prizewinners he would not have to lay down his gun to pick up the prize. Yet you say it shouldn't be given because it might be offensive to the bureaucracy of the Soviet Union. What utter hypocrisy for such an editorial to appear at such a time.

Yours faithfully,

FRANK SORENSON

Corvallis, Oregon,  
USA

# news and views

## High resolution interferometry

from F. G. Smith

THE angular accuracy of radio astronomical maps of celestial objects has progressed beyond all optical measurement, but it has reached a natural limit. This limit is provided by the available intercontinental distances between the component radiotelescopes used in Very Long Baseline Interferometry (VLBI). The observations reported on page 17 use multiple baselines between the 100-m radiotelescope in Germany and three American radiotelescopes, at Green Bank, Owens Valley, and Fort Davis. At a wavelength of 2.8 cm a source diameter of only  $0.25 \times 10^{-3}$ " can be resolved by this multi-element interferometer, which uses all of the six independent baselines between the four telescopes. The combined efforts of 13 radioastronomers, and doubtless many supporting staff, at these telescopes now give us a map of the central radio source in the galaxy NGC1275, well known optically as a Seyfert galaxy with very large internal velocities. The radio map only covers the nucleus of the galaxy, with a total extent of 5 pc, but the resolution is 0.1 pc. Longer

wavelength radio emission, as mapped by the 5-km radiotelescope at Cambridge, comes from much more extensive regions, while the whole galaxy extends to a diameter of more than 50 kpc. It is the very core of the galaxy that is being explored in this new map.

The technique of VLBI does not give the same full and unambiguous map as does aperture synthesis. For example, the nucleus of NGC1275 is elongated, with components whose sizes, shapes and relative dispositions are now fairly well determined: but it would be equally possible for the whole map to be rotated by  $180^\circ$ . This is of no consequence in the physics of this radio source, which is known to be active on a very short time scale. Most of the radio emission has appeared during the last 15 yr, since the time that measurements started on short wavelengths.

Rapidly changing radio sources present further problems in interpreting VLBI measurements. If a single baseline is used for measuring an apparent

source diameter, the source can appear to grow or shrink alarmingly rapidly.

An effect of this sort has even led to the suggestion that some components of radio galaxies are expanding outwards with velocities greater than that of light. Such an interpretation requires the various components of a source to retain their relative intensities, and to change only their relative positions. The isolation of several small components within the nucleus of NGC1275, which must be the seat of the large intensity changes observed since 1960, suggests that it is premature to interpret any changes of configuration of radio galaxies as due to "super-light" velocities.

The physical processes in the nucleus will provide much food for thought. Large parts of the galaxy are moving with relative velocities of over  $3,000 \text{ km s}^{-1}$ . Many theorists consider that the kinetic energy of this motion comes from an explosive event in the nucleus, where the radio emission now demonstrates the active generation of high energy particles and magnetic fields.

## Behaviour of the ionosphere and plasmasphere during geomagnetic storms

from T. B. Jones

THE interaction of the solar wind with the Earth's outer environment involves complicated processes many of which are not yet fully understood. The geomagnetic and ionospheric storms produced by enhancements of the solar wind are particularly interesting since they give rise to major changes in both the ionosphere and magnetosphere. These in turn, disrupt long range radio communications and navigation systems which depend on the reflection of radio waves from the ionosphere.

Solar disturbances frequently produce an increase in the velocity and concentration of the particles of the solar wind. When this enhanced wind

reaches the Earth's magnetosphere it produces several phenomena which include modification of the Earth's field, increased auroral activity and marked changes in the electron density distribution of the ionosphere. The arrival of the enhanced solar wind at the magnetosphere boundary increases the compression of the geomagnetic field which is observed as a sudden commencement geomagnetic storm on the Earth's surface. Simultaneously, the number of energetic particles in the magnetosphere trapping regions increases as particles are injected into the magnetosphere by transport across the magnetic shells. The increased ring current due to the particle enhance-

ment is responsible for the main phase of the storm. A detailed account of the dynamical processes which govern the behaviour of the trapped particle belts can be found in *Particle Diffusion in the Radiation Belts*, (Schulz, Lanzerotti and Roederer, Springer-Verlag, 1974).

Changes of shorter duration known as 'polar substorms' can occur in the polar magnetic field. These disturbances are a feature of the 'auroral oval' which corresponds to the region where the field lines that leave the Earth's surface stretch out into the magnetotail. The role of the north-south component of the interplanetary magnetic field in substorm processes

has been the object of some controversy. It is generally thought that the southward turning of the field leads directly to a series of growth processes which trigger the substorm. On the other hand measurements in Alaska indicate that substorms occur frequently even when the field component is directed northwards. This conflict has been resolved by Akasofu (*Nature*, **286**, 191; 1975) who suggests that the occurrence of a substorm depends neither on the field direction nor on its rate of change, except that if a steady northward field ( $>6$  h) is established then no substorms are observed. During these events energetic particles travelling along the magnetic field lines penetrate into the lower ionosphere where they produce ionisation enhancements in both D and E regions which greatly affect the propagation of radio waves through these regions. It has been suggested that even lower levels of the atmosphere are influenced by geomagnetic storms. Olson (*Nature*, **257**, 113; 1975) has found that at tropospheric heights, the 500 mbar vorticity index, which is a rough measure of cyclonic activity in the Northern hemisphere, decreases during the main phase of a storm.

Storm-induced disturbances are not confined to polar latitudes and the F region of the ionosphere is affected even at the magnetic equator. Both increases and decreases in this layer's electron density are observed depending on the particular storm event. The detailed mechanisms of F region storms have been discussed by Rishbeth (*J. atmos. terr. Phys.*, **37**, 1055; 1975) and changes in thermospheric circulation are shown to be a major factor in producing the observed ionospheric disturbances. In principle, both positive and negative storms can be caused by circulation changes though it is likely that other factors such as electromagnetic drift, ionosphere-magnetosphere plasma flux and the effects of propagating gravity waves have important roles especially at low latitudes. Storm-induced exchanges of ionisation between the ionosphere and protosphere have been observed by Soicher in a recent satellite experiment (page 33, this issue).

In view of the complexity of the storm processes there is an urgent need for further measurements of particle fluxes, magnetic field variations and ionisation changes. An international cooperative effort to obtain these observations will be made during the forthcoming International Magnetosphere Study (IMS), period 1976 to 1978. A wide range of ground based and space vehicle techniques will be deployed in a coordinated programme to study the magnetosphere and its

influences on other regions of the Earth's environment. □

## Weak gamma-ray bursts

from A. C. Fabian

SOURCE counts are widely used by astronomers working in all parts of the spectrum, and appear under various names and guises. Comparisons of the number of faint sources with brighter ones can yield information on the geometrical distribution of sources in space, their evolution with time, cosmological effects and the distribution of absorbing material. This information is gained without any precise knowledge of the distances to the sources. Unfortunately, however, source counts do not give unique solutions to problems. This is mostly due to the fact that there is always some spread in the intrinsic luminosities of the sources.

The latest category of events to be counted are cosmic gamma-ray bursts. These are the enigmatic flashes of gamma radiation first detected by the Vela satellites. The only facts really known about them are that they show complex structure on time scales of hundredths of seconds to tens of seconds, their spectra somewhat resemble those expected from thermal bremsstrahlung from regions of temperature  $\sim 10^8$  K, and their origins lie outside the inner Solar System. Counts of the more intense bursts detected by the Vela and other satellites, with integrated fluxes greater than  $\sim 10^{-4}$  erg  $\text{cm}^{-2}$ , suggest that they are relatively uniformly distributed in space. The rate is such that weaker events ( $\sim 10^{-7}$  erg  $\text{cm}^{-2}$ ) are predicted to occur several times per hour. Such a prediction is testable by balloon-borne detectors, and Bewick, Coe, Mills and Quenby of Imperial College London have recently reported the results of a series of flights (*Nature*, **258**, 686; 1975).

Only one event was observed, of size  $1.2 \times 10^{-7}$  erg  $\text{cm}^{-2}$ , in 13.5 h of observing time. This is a significantly different rate to that predicted. In the authors' opinion it suggests that a uniform source distribution can be excluded. Such a result might be expected if the sources are galactic, for then there might be fewer weaker sources observed in directions perpendicular to the galactic plane. Cosmological effects—principally redshift—might be invoked if the sources of gamma-ray bursts are extragalactic. Some caution is appropriate in interpreting the results, however, since

event rates are being compared between different detectors of somewhat uncertain apertures, efficiencies and energy ranges. Consequently there are errors in the integrated fluxes that are difficult to estimate. The Imperial College detectors appear to be sensitive enough to avoid limitations due to the transient nature of the bursts. This would only become serious if a substantial fraction of the bursts had timescales of 10 s or more, but there is at present no indication of this being so.

There are undoubtedly many other groups building or flying balloon-borne detectors to monitor weak gamma-ray bursts. It is hoped that these will confirm the first results and will eventually define the shape of the size distribution of weak gamma-ray bursts. The rare stronger bursts will probably only be available for study by satellite detectors. We are still no closer to a theoretical interpretation of gamma-ray bursts, although it is notable that the number of theories proposed to explain them is now lagging behind the number of detected events. □

## Fish that change sex

from John R. Krebs

To a narrow-minded mammal the sex life of the Blue-headed Wrasse, a tropical reef fish, may seem odd. The Blue-headed Wrasse occurs in two colour phases: smaller fish are highly variable in colour and may be either male or female; while larger, older individuals are always blue and green with two vertical black stripes, and are invariably male. Some individuals go through the first (initial phase) colour pattern as a female and turn into a male when they reach the striking terminal colour phase. Other individuals go through both phases as a male. The transition from initial to terminal colour phase and the accompanying sex change can be achieved rapidly. If all the terminal phase males are taken away from an area of reef, initial phase males or females soon start to change colour and become terminal males.

Most of the fertilising of females is done by terminal males. They set up temporary territories at around midday at a specific spawning site on the reef. Here they wait for females to turn up, while the smaller initial phase males mill around in large numbers (often in hundreds). When females arrive at the spawning area they prefer to mate with the territorial terminal males, and a lucky male may mate up to 100 times a day. Initial phase males sometimes manage to fertilise a

NITROGEN fixation commonly occurs in bacteria only when the oxygen tension is low either because the nitrogen fixer is an obligate anaerobe such as *Clostridium* or because the aerobic organism, *Azotobacter* for example, has in addition to the normal ATP synthesising system, a very active electron transport chain that operates without conserving energy. This results in a micro-aerobic environment around the site of nitrogen fixation (Postgate, in *Biological nitrogen fixation*, edit. by Quispel, A., 1974) and brings about a respiratory protection of the nitrogenase.

The nitrogen-fixing blue-green algae have a particular problem since their photosynthesis leads to oxygen evolution; they may fix nitrogen only at low oxygen tensions and low light intensity (non-heterocystous forms) or they may segregate their nitrogenase into special compartments (the heterocysts) to which the fixation of nitrogen is normally confined. Only under artificial conditions of anaerobiosis do the ordinary vegetative cells of heterocystous blue greens have active nitrogenase.

Heterocysts are specialised in that they seem to lack the oxygen-evolving component of photosyn-

thesis, photosystem 2. They may also remove unwanted oxygen diffusing in from the environment by the use of an active respiratory chain. Thus a low oxygen tension could be maintained at the site of nitrogen fixation.

The absence of photosystem 2 has been deduced from the lack of accessory pigments, from the low yields of chlorophyll fluorescence and from the inability of heterocysts to fix carbon dioxide (Stewart, *A. Rev.*

## Nitrogen, oxygen and manganese

from F. R. Whalley

*Microbiol.*, **27**, 283; 1973). The association of photosystem 2 with manganese has also been widely documented (for a review see Cheniae, *A. Rev. Pl. Physiol.*, **21**, 467; 1970) although the evidence has always been indirect. Recently Tel-Or and Avron (*Proc. third int. Congress on Photosynthesis*, 569; 1974) reported isolation of a heat stable manganese-containing compound of small molecular weight which, when added back to depleted particles isolated from a blue-green alga (*Phormidium luridum*) restored oxygen evolving ability, thus

providing direct evidence of a role for manganese in O<sub>2</sub> evolution.

The lack of photosystem 2 in heterocysts in another blue-green alga (*Anabaena cylindrica*) is now further substantiated (Tel-Or and Stewart, *Nature*, **258**, 715; 1975), following an examination of the distribution of <sup>54</sup>Mn between vegetative cells and heterocysts isolated from cultures grown with <sup>54</sup>Mn. This showed a correlation between the presence of <sup>54</sup>Mn, the Mn:chlorophyll ratio, and the ability of the isolated cells to evolve oxygen. The clear conclusion is that heterocysts of these nitrogen-fixing algae are deficient in manganese, that they lack a functional photosystem 2 and therefore cannot evolve oxygen. Heterocysts are thus specially adapted for nitrogen fixation. By contrast, the vegetative cells accumulate manganese and evolve oxygen but do not appear to fix nitrogen. It is of correlative interest (Anderson *et al. Biochem. biophys. Res. Commun.*, **17**, 685; 1974) that fractions of isolated chloroplasts which have been depleted in photosystem 2 also become depleted in bound manganese whereas those enriched in photosystem 2 become enriched in manganese.

female's eggs by dashing into a territory at the last moment. More often, they chase an arriving female as a group and achieve a sort of piscine gang bang.

The facts are remarkable enough, but what is the evolutionary explanation for this strange reproductive system? Warner, Robertson and Leigh (*Science*, **190**, 633-638; 1975) develop an idea of M. T. Ghiselin, who argued that natural selection will favour sex change whenever the reproductive potential of one sex increases rapidly with age while the other remains fairly constant. In this circumstance it will be advantageous to start life as the sex which does not benefit from being older (or to put it another way, does not suffer from being young) and switch to the other sex at a later stage. This is what seems to be happening in the Blue-headed Wrasse. Terminal males have an enormous reproductive potential, while initial males have a low mating success, so an individual can get the best of both worlds, by starting off as a female (young females do not suffer any penalty for youth) and switch to being a male at a later stage when it can successfully defend a mating territory. But why do some individuals go through the initial phase as a male and not a female? Warner *et al.* suggest that in large populations, where many females arrive simul-

taneously at the spawning area, the opportunities for an initial phase male to grab the odd fertilisation are high enough to make being a male in early life about as profitable as being a female. Their data show that the daily mating rates of an initial male and a female in a large population are about the same. In a small population, however, there are fewer chances for the initial males. There are rarely enough females at the spawning site to enable an initial male to steal a fertilisation. As this account would predict, initial males are much rarer in small populations than in large ones. Also, in other wrasse species that always occur in small groups, initial phase males are always rare.

If, as Warner *et al.* suggest, sex change is an optimal strategy when there is a big advantage in being old in one sex but not in the other, why don't mammals such as seals, deer and baboons, in which the older males monopolise females, change sex like the wrasse? The authors suggest that one or more of three factors may prevent them from doing so: the physiological cost of changing sex in an animal with internal fertilisation, the rigidity of the mammalian sex determination system, and the fact that in mammals competitive experience as well as size is important in determining the reproductive superi-

ority of older males. Obviously this experience would be lost if a male spent its youth as a member of the opposite sex. □

## How old are cosmic rays?

from J. J. Quenby

WHILE recent progress in observational astrophysics has been rapid, the answer to the fundamental question as to the origin of cosmic radiation remains elusive. This flux of relativistic, charged particles populates the Galaxy with an energy density sufficient to influence significantly the dynamics of the whole system, but we do not know whether relatively near objects like the Crab Nebula or distant, energetic objects like strong radio galaxies constitute the prime source. An important clue would lie in an ability to 'read' the <sup>10</sup>Be 'clock' in the cosmic ray flux. The light elements Li, Be and B are rare in cosmic material and should not be present at the source of particle acceleration. By knowing production cross sections for the light elements in collisions between nucleons and atoms it is possible to calculate the amount of material through which the average

cosmic ray must have passed in order to produce the observed elemental abundance in the radiation. Then by finding the amount of radioactive  $^{10}\text{Be}$ , which has a half-life for decay of  $1.5 \times 10^6$  yr, relative to other light nuclei abundances, the actual cosmic ray age is deduced. If cosmic rays are not of Universal origin, that is to say, if they do not fill extra-galactic space as they do the Galaxy, then they must be confined either to the region of the galactic disk or galactic halo. The latter is an approximately spherical region, including the stellar disk, maintained by magnetic fields which trap charged particles and cause radio emission. By cosmic ray life we mean their time to diffuse or leak from the confinement region, although some are lost catastrophically by nuclear collision with the material of the trap. Present estimates allow a cosmic ray life of a few  $10^6$  years if confinement is to the disk, or alternatively a life in excess of  $10^7$  years if confinement is to the halo.

Satellite data on the  $^{10}\text{Be}$  abundance obtained by Garcia-Munoz, Mason and Simpson of Chicago University (*Astrophys. J. Lett.*, **201**, L141–144; L145–148; 1975) suggests a halo rather than a disk confinement. These workers employed small charged particle telescopes mounted on the IMP-7 and IMP-8 satellites which sampled interplanetary conditions. Isotopes were separated to an accuracy of 0.4 atomic mass units by looking at energy loss in two solid state detectors and residual particle energy in a crystal scintillator. They found few or no  $^{10}\text{Be}$  particles although  $^7\text{Be}$ ,  $^9\text{Be}$  and  $^{10}\text{B}$  events were detected.

If accepted, these interesting results will ease a related problem, concerned with the anisotropy in galactic arrival directions of the cosmic ray flux. Although an asymmetry of roughly 0.01% seems to be present, according to Imperial College measurements, the demands on the magnetic scattering process for a disk confinement model are severe. The short total path length requires a large amount of scattering to keep the anisotropy small and this in turn causes a large energy drain as the charged particles interact with the scattering centres. Halo confinement means less scattering and hence less energy drain. Alternatively the small anisotropy would be thought to imply a universal cosmic ray flux.

Although the Chicago group have certainly developed a high-quality experimental technique, some difficulties remain with the result. To date Balloon groups at Goddard Space Flight Center and the University of New Hampshire have also achieved isotopic resolution in the light element range, but they report  $^{10}\text{Be}$  fluxes twice or four times those suggested by the satellite data. It

could be, however, that interactions above the balloon or magnetospheric processes have influenced the balloon results. Another point is that the lifetime deduced depends on assumptions as to the cosmic ray source spectra and these have to be obtained from trial models for the motion and interactions of cosmic rays in the confinement region. Furthermore, the final result clearly depends on the allowance made for solar modulation in the interplanetary medium. Diffusion and energy loss effects due to the interplanetary magnetic field tend to enhance the amount of  $^{10}\text{Be}$  observed relative to neighbouring nuclei. At present we do not know whether the total cosmic ray flux at Earth is close to the interstellar value or as much as six times lower. If the modulation is small then even the Chicago  $^{10}\text{Be}$  flux would be consistent with disk confinement and life of a few  $10^6$  yr for cosmic rays. Thus our final reading of the  $^{10}\text{Be}$  'clock' will depend on further studies to determine the scattering power of the interplanetary medium. A definitive answer probably requires a direct measurement of the interstellar cosmic ray flux, but this may not be achieved with planned missions in the ecliptic plane to Uranus and beyond. Indeed the lack of noticeable change in the cosmic ray intensity on the way out to Jupiter, as recorded by Pioneers 10 and 11, is one of the puzzles which illustrate our lack of understanding of modulation. Perhaps an off-ecliptic mission to solar polar latitudes where cosmic ray access is thought to be easier is the correct experiment for determining the  $^{10}\text{Be}$  abundance. □

## The Red Queen dethroned

from A. Hallam

IN recent years there has been an increasing tendency in some circles to investigate the evolutionary record of fossils in terms of general rules and processes without regard to specific causes operating on specific taxa. Van Valen (*Evol. Theory*, **1**, 1; 1973) has made a notable contribution in this respect by applying the survivorship curve technique of population biologists to the study of extinction rates for numerous fossil taxa. Van Valen claimed to demonstrate a general approximation to linearity in his curves, which are cumulative frequency distributions of taxonomic durations with logarithmic ordinates. This led him to propose a new evolutionary "law", which, in brief, states that within a relatively homogeneous higher taxon,

subtaxa tend to become extinct at a stochastically constant rate. As an explanation Van Valen put forward what he termed the Red Queen's hypothesis (because of the Lewis Carroll character who found it took all the running one can do to keep in the same place). In concise terms, the hypothesis states that increase in the momentary fitness of any set of species within a specific adaptive zone acts to reduce the fitness of all other species within that zone, in such a way as to cause the effective environment of all the species to deteriorate in a stochastically constant manner through time.

Van Valen's work has aroused considerable interest and provoked active discussion. Foin *et al.* (*Nature*, **257**, 515; 1975) criticise his use of survivorship curves because of the confusion between two quite different methods of analysis and because of the weakness of the analogy between cohorts of organisms born together and taxa which arose at different times. On the other hand Raup (*Paleobiology*, **1**, 82; 1975) generally approves of Van Valen's approach but suggests some methodological improvements; he does not attempt to decide whether or not the proposed law is correct. Another criticism of Foin and his coworkers is that the level of aggregation of the fossil data is so high that it is bound to eliminate all but the most extraordinary events, and apparently log linear survivorship curves are therefore inevitable. To this Van Valen replies that this averaging effect is a positive advantage since it eliminates "noise". He also attempts to clear up a conceptual confusion among his critics. He has never made the sweeping statement that the probability of extinction of a given taxon is independent of age, but argued instead that the mean extinction probability of a group is constant over long periods of time.

Salthe (*Paleobiology*, **1**, 356; 1975) is another who is unimpressed with Van Valen's "law". A stochastic approach to constancy of extinction rates merely signifies that there have been no systematic forces operating on the organisms in question, so that in fact there is nothing that requires explanation in any causal sense. The apparent constancy of extinction has, however, been thrown into question by the methodological analysis of Seposki (*Paleobiology*, **1**, 343; 1975). Seposki points out that the durations of taxa cited by Van Valen are in effect time interval estimates and these time intervals vary in length, approximating to a lognormal distribution. The resultant effect is to impart a systematic bias to the palaeontological data such that linearity, implying constancy of extinction rate, is approximated in the taxonomic survivorship curves. When

corrections are applied, it is estimated that, of Van Valen's 82 survivorship curves for extinct taxa, only 12% are definitely linear. Evidently Van Valen cannot win. Either his results show linearity, which is held to be biologically without significance, or most do not, in which case his "law" breaks down.

Although it begins to look as though the Red Queen has been toppled from her throne, the criticism directed at Van Valen's work should not be held to detract from an original, perceptive and imaginative attempt to glean more from the fossil record than a more conventional approach would allow. It has been stimulating in the best sense and may yet lead to important new advances in our understanding of evolution. That it appeared in the first issue of an obscure journal with limited circulation lends support to the view that if a paper is sufficiently interesting it will be widely read, regardless of where it was published. □

## Strong absorption in $^{40}\text{Ca}$ - $^{40}\text{Ca}$ elastic scattering

from P. E. Hodgson

MANY studies of the elastic scattering of heavy ions have now been made, and it is usually found that the differential cross section has a diffraction structure that varies smoothly with the incident energy and is well described by the optical model.

A notable exception to this behaviour was found some years ago by Bromley *et al.* (*Phys. Rev. Lett.*, **19**, 369; 1967; *Phys. Rev. Lett.*, **20**, 175; 1968): the cross section for  $^{16}\text{O}$ - $^{16}\text{O}$  elastic scattering shows a very irregular behaviour as a function of incident energy. This is in marked contrast to the corresponding data for  $^{18}\text{O}$ - $^{18}\text{O}$ , which varies smoothly with energy as expected.

This early work, together with subsequent studies, showed that this notable difference in behaviour is determined by a balance between the strong absorption of the lower partial waves and the weaker absorption of the higher partial waves. For heavy ion collisions many features of classical behaviour remain, so that partial waves correspond to the interactions at different radial distances: the lower to interactions inside the nucleus and the outer to interactions in the nuclear surface and beyond. The scattering is thus determined by the absorbing part of the optical potential, and it was found that the observed behaviour could well be reproduced by allowing

the strength of the absorption to depend on the orbital angular momentum quantum number  $L$ , being strong for small  $L$  and weak for large  $L$ .

More physically, it was shown that the absorption is mainly due to the direct reactions strongly coupled to the entrance channel. When there are many of these, the nuclear surface is nearly opaque and one observes the small structureless cross section strongly decreasing with energy—behaviour typical of strong absorption. This is the case for  $^{18}\text{O}$ - $^{18}\text{O}$ , which has two neutrons outside the stable  $^{16}\text{O}$  core that can be excited and transferred in many ways, leading to many possible reaction channels.

The situation is quite different for  $^{16}\text{O}$ - $^{16}\text{O}$  which is stable and difficult to excite and so absorbs weakly. Each partial wave makes its own particular contribution, giving the strongly-marked fluctuations in the cross section as a function of energy.

This explanation accounts for all the data in the oxygen region, but it is clearly desirable to confirm it by measurements on other nuclei. It is increasingly difficult to make measurements on heavier nuclei because the strong coulomb repulsion must be overcome before the nuclear interactions can take place, and this requires high incident energies.

The next lightest nucleus after  $^{16}\text{O}$  that has a very stable doubly-closed shell structure is  $^{40}\text{Ca}$ , and so it is desirable to make measurements of  $^{40}\text{Ca}$ - $^{40}\text{Ca}$  scattering. This has recently been done by Doubre *et al.* (*Phys. Rev. Lett.*, **35**, 508; 1975) at Orsay in France, and some of their results are shown in the figure.

It is notable that, contrary to ex-

pectation, the cross sections fall smoothly with increasing energy, so characteristic of strong absorption. An optical model calculation with an absorption increasing with energy agrees well with the experimental data. The physical explanation of this result is not clear. The explanation used in the oxygen region fails for calcium, and it may be that the density of states in the appropriate region of excitation is sufficiently high in the calcium case for the required absorption to occur. More measurements are in progress to provide data for a more comprehensive study of these effects. □

## Dominance and diversity

from Peter D. Moore

By far the most frequently used index of diversity in studies of plant communities is that derived from Shannon and Weaver's information theory, in which,

$$H' = -\sum p_i \ln p_i,$$

where  $p_i$  is the proportion of the total number of individuals (or biomass) belonging to the  $i$ th species. This index is a function of both species richness and evenness (the apportionment of individuals or biomass amongst species). The feature of plant communities to which the index responds most effectively is the presence of one or more dominant species. This results both from the consequential inequitable arrangement of biomass or numbers in the community and from the reduction in species number which often accompanies the assertion of dominance by certain members of the community. When one speaks, therefore, of high diversity in plant communities, one is often in fact referring to a lack of dominance.

Because of this it is unwise to assume that diversity changes as a consequence of a particular management practice, such as the abandonment of arable land, or the disturbance of equilibrium communities, can be easily predicted. Such unpredictability is a feature which has been demonstrated in two recent pieces of work in the United States concerned with precisely these situations. Tramer (*Ecology*, **56**, 905; 1975) has studied selected plots on abandoned agricultural land in Ohio over a period of four years and has attempted to document changes in plant species diversity. Numerically based diversity was highest in the second year after abandonment and subsequently fell to a lower level, while biomass-based diversity declined steadily over the four year period. This

Differential cross section for  $^{40}\text{Ca}$ - $^{40}\text{Ca}$  elastic scattering at three angles as a function of energy and compared with optical model calculations.

process can be accounted for by the importance of biennial species in the second year and the subsequent assumption of dominance by the perennials *Aster pilosus* and *Solidago altissima* in the third and fourth year. There is certainly no indication that the popular conception of diversity increasing with succession applies here, but the observations are very short term from a successional point of view.

The dominance of large, perennial plant species in a community must, by its very definition, reduce species diversity. Successional developments involving invasion by such species can therefore be expected to show an accompanying decline in diversity. It is also true that the application of any additional stress, which reduces the performance of a potential dominant, serves to increase diversity, as has been demonstrated by Grime (*Nature*, **242**, 344; 1973) for both man-induced stresses and for natural environmental extremes. One such stress is that of predation, and the experiments of Paine (*Am. Nat.*, **103**, 65; 1966) showed how predation pressures serve to maintain diversity in intertidal communities. The same process operates in terrestrial plant communities grazed by herbivores (see Harper, *Brookhaven Symp. Biol.*, **22**, 48; 1969).

It is this complex interaction of grazing intensity and plant species diversity which provides an explanation for some of the data which Platt (*Ecol. Monogr.*, **45**, 285; 1975) has derived from his study of the recolonisation of areas of prairie disturbed by badgers. He selected for study the abandoned diggings of badgers which had been recovering for at least three years and compared their plant cover with that of the surrounding, undisturbed prairie. In virgin prairie areas, the badger mounds often had more species per unit area, but had a slightly lower overall diversity than their surroundings. This could be related to the important role played by *Andropogon gerardi* on the mounds, which was not observed to the same extent in surrounding areas. Overgrazed prairie regions bore a different plant community in which the grass *Poa pratensis* was dominant, at times accounting for 60% of the above-ground biomass. The diversity of such overgrazed prairie was found to be very much lower than that of virgin areas. Badger mounds in the overgrazed prairie, however, had as high a species diversity as those in virgin areas and were therefore considerably more diverse than surrounding communities. This was the consequence of a reduction in the importance of *Poa pratensis* (to about 20% of the biomass) and also a higher species richness.

Once again the question of successional development is seen to be

irrelevant to the determination of overall plant community diversity, except in that it may relate to the development of dominance. Any factor, whether related to succession or imposed by some external stress, which reduces the establishment or growth rate of potentially dominant, perennial plants, will enhance the species diversity of the community. □

## Hydrothermal activity off-ridge?

from Peter J. Smith

THERE is now considerable evidence to suggest that metalliferous oceanic sediments are generally the result of hydrothermal activity. It is implicit in the close association of most such sediments with submarine volcanism, for example, that the added metals are precipitated from metal-rich solutions produced by the reaction of seawater with cooling magma. In practice, the association with submarine volcanism means that many enriched sediments have been observed in the vicinity of active oceanic ridge crests, for it is there that the bulk of the Earth's volcanic activity occurs. But there are exceptions; metal-rich deposits have been found in, for example, the Bauer Deep. What, then, is the origin of these off-ridge enriched sediments?

As the Bauer Deep lies immediately between the extinct Galapagos Rise and the active East Pacific Rise, it can hardly be said to be totally removed from a ridge environment. One possibility therefore is that the metal-rich deposits (as indicated by high transition metal to aluminium ratios) were formed along the East Pacific Rise by hydrothermal processes and subsequently carried across the rise flank to the Deep. But as Dymond and Veeh (*Earth planet. Sci. Lett.*, **28**, 13; 1975) now point out, there are other possible explanations. There could be a single, wide hydrothermal zone, centred on the East Pacific Rise and encompassing the Bauer Deep, within which the metal/aluminium deposition varies. Alternatively, the Rise and the Deep could be associated with separate hydrothermal systems. Or the Rise crest sediments could be hydrothermal and the Deep sediments largely authigenic.

In an attempt to determine which, if any, of these models is the correct one, Dymond and Veeh have analysed metal accumulation rates in cores from the East Pacific Rise crest, the flanks of the Rise and the Bauer Deep. The role of aluminium in marine environments is poorly understood, and so the significance of variations in the transition metal/aluminium ratio itself is difficult to assess. Nevertheless, the separate

patterns of accumulation rates of Fe, Mn and Al across the Rise-Deep zone seem to be inconsistent with the patterns expected from a wide hydrothermal region. The observed patterns all peak in the Deep as well as at the Rise, suggesting that the idea of a slow decrease in hydrothermal activity from the Rise outwards cannot be valid.

The peaking across the Deep also rules out a more rapid fall of hydrothermal activity away from the Rise in conjunction with completely authigenic precipitation in the vicinity of the Deep. Estimates made by Dymond and Veeh suggest that 30-50% of the manganese and all of the nickel in the Bauer Deep could in fact be deposited by authigenic processes; and given the errors on these estimates, this means that an authigenic origin for most of the minor transition metals cannot be ruled out. But the same cannot be said for iron. The amount of iron present is such as to eliminate authigenic activity as a primary source, even if it is allowed that some of the iron could be detritus from land-derived clays and volcanic debris.

This then leaves two models: the double (Rise and Deep) hydrothermal source and the single (Rise) source with transport of metal-rich sediment to the Deep. Unfortunately, since the two models give similar distributions of metals, it is not possible to distinguish between them on the basis of Fe and Al accumulation rate data alone. Although there is a maximum in metal accumulation over the Deep, there is apparently no comparable maximum on the opposite side of the Rise. This would seem to argue against a single source with transport, except that preferential transport of material away from the Rise in one direction cannot be ruled out (especially as knowledge of the bottom currents in the area is poor).

Then again, Anderson and Halunen (*Nature*, **251**, 473; 1974) have argued in favour of hydrothermal processes in the Bauer Deep on the basis of heat flow data, suggesting that such processes could have been initiated when spreading moved from the Galapagos Rise to the East Pacific Rise about 6.5 Myr ago. On the other hand, one of the Deep cores examined by Dymond and Veeh is probably about 20 Myr old; and persistent hydrothermal activity since this core was formed seems unlikely.

There is thus evidence (that given above and more) on both sides. Moreover, there are data suggesting that neither model is entirely correct. There are, for example, chemical differences between East Pacific Rise and Bauer Deep sediments, although many, if not all, of these could be explained on the basis of simultaneous authigenic depo-

sition in the Deep. For the time being the detailed picture remains unclear. What is certain, however, is that the rate of accumulation of metals in the Bauer Deep is an order of magnitude lower than that on the East Pacific Rise. □

## "Turn-coat" trypanosomes undressed

from J. R. Baker

It has been known for some time that the tsetse-transmitted trypanosomes of Africa (including *Trypanosoma brucei*, which causes human sleeping sickness) have, at certain times in their life cycle, a 12–15 nm thick "coat" outside their unit plasma membrane. Mainly circumstantial evidence strongly suggested that this coat contained antigens presented to the vertebrate host which, by being structurally changed every time the host produced a specific antibody, contributed to the parasites' survival and, hence, the eventual death of the host (Vickerman, *Ciba Symposium*, **25**, 53; 1974) and also to our inability to produce an effective anti-trypanosomiasis vaccine.

A few years ago, Wright and Hales in Toronto (*J. Parasit.*, **56**, 671; 1970) suggested that the coat consisted of carbohydrate and protein, and work by them and Lumsden (*J. Cell Sci.*, **6**, 285; 1970) led to the idea that the trypanosomes may cast off old antigen by releasing long tubular threads of encoated plasma membrane (though the natural production of these threads *in vivo* has never been conclusively demonstrated). In Basel, Steiger produced evidence that new coat was produced by the trypanosomes' Golgi-derived reticulum (*Acta trop.*, **28**, 341; 1971 and **30**, 64; 1973). This study took an exciting step forward three years ago when Cross reported to the 13th Trypanosomiasis Seminar in London the isolation of a single glycoprotein apparently representing dissociated coat (*Trans. R. Soc. trop. Med. Hyg.*, **67**, 261; 1973). Significantly, the putative coat proteins prepared from different clones of one strain of *T. brucei* differed in composition. This supported the view that coat protein is the variant antigen, an idea now further strengthened by Cross's latest discovery that mice immunised with purified coat glycoprotein (molecular weight  $65,000 \pm 3,000$ ) are protected against subsequent infection with living trypanosomes of the same, but not of other, clones (*Parasitology*, **71**, 393; 1975). One of the major remaining problems concerns the cellular control of this antigen switch; it is insufficiently random to be explained easily by mutation and its occurrence within a

clone appears to preclude its resulting by selection from a pre-existent mixed population. Current thinking—stemming, incidentally, from work by Ehrlich and others in 1909 (*Z. Immunitätsforsch.*, **3**, 296; 1909)—favours a rather vague concept of induction by antibody. Cross's work may well prove to be an important key in the eventual unlocking of this mystery which, in turn, could conceivably lead to successful vaccination against sleeping sickness. □

## A hundred years ago

A REMARKABLY valuable discussion by M Belgrand, of the inundations of the Garonne, viewed specially in connection with the heavy rains which fell over France from the 21st to the 24th of June last, has been appearing at intervals for the past fortnight in the *Bulletin International* of the Paris Observatory. It is pointed out, from the dates of their occurrence, that the inundations of the southern portion of the basin of the Garonne which slants from the Pyrénées, have nearly always occurred in spring or early summer, and at the same dates either no floods at all, or comparatively unimportant floods, were experienced in the northern portion of the basin which slopes down from the Cevennes and central plateaux of France. It is to be noted that it is just at this season that the rainfall of the southern portion of France attains its annual maximum, and the nearer to the Pyrénées the more decidedly is the May–June maximum marked, and that the melting of the snows which have accumulated on the Pyrénées during the winter months proceeds most rapidly. On the other hand, it is shown that the great inundations of the northern portion of the basin occur generally during the cold months of the year, and that at the time of their occurrence there have been no corresponding great floods at Toulouse, in the southern portion of the basin. It is during the cold season that the rainfall reaches its annual maximum on leaving the slopes of the Pyrénées and advancing northwards over the basins of the Tarn, Lot, and Dordogne. The disastrous inundation of June, 1875, was in accordance with the experience of previous floods in the south of France. As a great flood it was limited to the river courses sloping down from the Pyrénées; and the nearest approach to a great flood elsewhere was in the basin of the Argout, the most southern tributary of the Tarn, and it was the flood of this tributary which occasioned almost the whole of the flood of the Tarn. At such places as Auch, situated in a narrow valley, and where, consequently, the drainage area is small, the inundation was much less disastrous than at Toulouse and places similarly situated near the confluence of large affluents draining a wide extent of the country.

from *Nature*, **13**, January 6, 197, 1876

## Oscillating universe bounces back

from John Gribbin

THE biggest problem with the Big Bang theory of the origin of the Universe is philosophical—perhaps even theological—what was there before the bang? This problem alone was sufficient to give a great initial impetus to the Steady State theory; but with that theory now sadly in conflict with the observations, the best way round this initial difficulty is provided by a model in which the Universe expands from a singularity, collapses back again, and repeats the cycle indefinitely. Such models have been known since the earliest development of relativistic cosmologies in this century, but have been favoured with a revival of interest in recent years. The latest study provides some intriguing agreements with observation of the real Universe, but also poses some new puzzles (Landsberg and Park, *Proc. R. Soc. Lond.*, **A346**, 485–495; 1975).

Landsberg and Park consider a model universe composed of gas and radiation which are 'allowed to interact'; this incorporates features of standard cosmology (taking account of gravitation) and of statistical mechanics (which does not take account of gravitation). The resulting hybrid is, they suggest "too simple to be realistic", but does go a step further than the standard dynamic models of traditional cosmology. Both the gas and the radiation (assumed black body) are uniform, which is as good an approximation as in any other cosmology, where such incidentals as galaxies are generally taken as 'test particles' of no great account.

The first important result which emerges from this incorporation of thermodynamics into cosmology is that during both the expanding and contracting phases of the oscillating model entropy increases, so that the "arrow of time" is constant. To follow the repeated 'bounce' through the initial/final singularity Landsberg and Park cheat a little by simply reversing the collapse at very great density, so that it becomes an expansion with the same speed. This may not be entirely valid, since it carries over information from one cycle to the next, but because the collapse phase proceeds more rapidly than the preceding expansion, this means that successive cycles of the oscillation start out faster and faster, expanding to greater and greater radii before they collapse in their turn, with each cycle taking longer than the last. This behaviour is in line with that of earlier oscillating models, but even

though it always happens with the models they have calculated, Landsberg and Park cannot prove that it must happen.

Such behaviour could explain why our Universe seems to be so close to the dividing line between continued infinite expansion and just turning back into collapse at some future time. In the Landsberg-Park cosmology, successive cycles of expansion/collapse bring the model ever closer to this dividing line, and the closeness of our Universe to the "just bound" condition might suggest that it has already been through many cycles. So, like the best theories, this one makes a firm prediction: future observations should show that the Universe is indeed just bound, and not just unbound.

But there are two snags with the theory. First, if successive cycles expand to bigger and bigger radii, running the calculation backwards would suggest that the bounce itself started in some infinitesimal hiccup some large number of cycles ago, so we still have an origin problem but in a different form. Second, and perhaps more serious, if the closeness of the Universe to the "just bound" condition means that it has been through many cycles then there has been ample opportunity for entropy to increase following the constant thermodynamic arrow of time of the model. Yet the most obvious feature of our Universe is its low entropy; as Hermann Bondi has said "thermodynamic properties tend to be very deep and significant: the fact that our night sky is very black, with very bright points, the stars, in it, may be the profoundest piece of knowledge of the universe that we have". But these, of course, are just the kind of questions that a more sophisticated version of this simple model might be expected to tackle. □

## Rotation of planetary atmospheres

*from a Correspondent*

A meeting of the Royal Astronomical Society, Institute of Physics and the Royal Meteorological Society, held in London on November 28, 1975, provided interdisciplinary discussions of the atmospheric motions at all atmospheric levels.

STUDIES of atmospheric motions concern scientists from various backgrounds, whose research interests generally confine them to a small region of the entire atmosphere. Meteorologists, for example, are concerned with

the lowest levels which constitute the troposphere and stratosphere which extend from the surface to about 35 km for their studies of weather and climate; aeronomers are interested in the physics, chemistry and motions of the remaining portions of the neutral atmosphere; the stratosphere, mesosphere and thermosphere, which extend to about 100 km above the surface; while a third group study the ionised layers of the upper atmosphere. It may be scientifically convenient to partition the atmosphere in this way according to the dominant physical processes that occur. It is, however, of fundamental importance that we now study the whole atmosphere, and consider the energy transfers between these regions, so that we may determine whether external effects such as solar activity or stratospheric compositional changes could have any effect upon our climate in the troposphere.

By tracking orbiting satellites for more than a decade, D. King-Hele (Royal Aircraft Establishment, Farnborough) has found that Earth's atmosphere above about 100 km moves faster than the solid body of the planet. This is called "super rotation". The magnitude of the motion is highly variable, with altitude, latitude and time, although the largest value measured so far is about  $160 \text{ m s}^{-1}$  at an altitude of 240 km from tracking the COSMOS 344 satellite. The normal rotation at these levels would imply motions of  $100 \text{ m s}^{-1}$ . The Explorer 1 satellite has been tracked through two solar maxima, and suggested that the rotation rate decreased with a corresponding decrease in solar activity. Subrotational motions ( $\leq 100 \text{ m s}^{-1}$ ) have so far been found only in the afternoon period at these altitudes. H. Rishbeth (SRC Appleton Laboratory, Slough) indicated that there is inadequate information to construct a theoretical model in an attempt to explain these motions. Unlike the winds in the lower atmosphere, they were not in geostrophic balance at these levels. He indicated that the driving mechanisms would differ on a local basis (for example, the polar cap, auroral zone, equatorial latitudes) and an integrated measurement/theoretical programme was urgently required. The deposition of interplanetary matter, in particular meteoroids, has often been thought to be a possible additional heating source of the upper atmosphere. D. W. Hughes (University of Sheffield) showed however, that there is insufficient material to modify the upper atmospheric motions in any significant manner.

In the stratosphere, wave motions play a major role in modifying the atmospheric motions as discussed by

D. G. Andrews (University College, London; Meteorological Office). The equatorial region has been found to undergo a quasi-biennial oscillation (QBO) in which, in a period of about 26 months, easterly motions become reversed into westerly motions. He suggested that Kelvin waves with a 15-d period could account for the easterly flow, while a Rossby gravity wave with a 4-d period could be responsible for the westerly flow. Andrews also thought that tropospheric changes may influence these stratospheric motions through the vertical propagation of energy. A. White (Imperial College, London) discussed the importance of baroclinic eddies in the transfer of troposphere energy. He showed that the structure of the flow was sensitive to the pole-to-equator temperature gradient and that changes in this parameter would modify the flow, producing a different climatology. White's studies indicated that simple models may be constructed to study climatic change over time intervals of several decades, through the parameterisation of the heat transfer effects of these eddies.

Other planetary atmospheres exhibit super rotation features, whose understanding could assist in determining the dominant driving mechanisms of the corresponding features of the Earth's atmosphere. R. A. Plumb (Meteorological Office) discussed the rotation of the Venusian stratosphere which moves sixty times faster than the solid body of the planet, producing zonal winds of about  $100 \text{ m s}^{-1}$ . The motion is generated by the upward momentum transport by the thermal tide in the Venusian stratosphere, driven by solar energy absorbed by the opaque clouds whose tops occur at about 200 mbar. Similar thermal forcing could not occur in the Earth's atmosphere, since most of the solar radiation is absorbed at the surface. Jupiter and Saturn also exhibit equatorial jets with zonal velocities of about 100 and  $400 \text{ m s}^{-1}$  respectively. R. Hide (Meteorological Office) stated that currently available theories were unable to account for these features.

This meeting emphasised the importance of the transfer of energy between atmospheric regions in explaining many of the observed motions. A more detailed understanding of the atmospheric dynamics requires further observations at all levels, which for the Earth's atmosphere is possible through the presently planned satellite and rocket programme as D. Rees (University College London) described. We may then expect further tripartite meetings of this type which are an invaluable forum for discussing the motions of planetary atmospheres. □

*The radio nucleus of NGC1275 (3C84) is found to consist of three apparently stationary centres of emission extending over 0.006" (3 pc) along position angle  $-9^\circ$ . One or more of these centres have changed their intensity or size in the last 3 yr. A preferential direction of alignment of both the small scale and large scale radio features as well as the optical features suggests a common cause of alignment operating over linear distances from a few pc to  $> 100$  kpc.*

NGC1275 is an active radio galaxy and is one of the strongest extragalactic radio sources at centimetre wavelengths. The radio nucleus has been previously studied by very long baseline interferometer techniques<sup>1-5</sup>, and has been shown to have a complex angular structure  $\sim 0.006''$  in extent and elongated along position angle  $\sim -10^\circ$ . Because the radio nucleus has a relatively large angular size and a high brightness, it is uniquely suited for detailed high-resolution observations. The earlier measurements, however, had an insufficient number of antenna pairs and insufficient resolution to map the complex structure in any detail.

### Intercontinental interferometer system

We report here new observations made at epoch 1974.5 with a 4-element intercontinental interferometer system which gave six simultaneous independent interferometers. The

observing frequency was 10,650 MHz ( $\lambda = 2.8$  cm) giving a maximum baseline of  $290 \times 10^6 \lambda$ . This was sufficient to resolve a Gaussian source of  $0.00025''$ . The polarisation was left-circular.

The elements of the interferometer are described in Table 1 and the diurnal track of each interferometer in the Fourier transform ( $u, v$ ) plane is illustrated in Fig. 1. Data were recorded at each station on an NRAO Mk II VLB terminal, and the tapes were correlated on the NRAO processor<sup>6</sup>. A description of the further averaging of the data, the calibration of the fringe amplitude and the experimental errors has been given elsewhere<sup>7</sup>.

### Derivation of source structure

The observed data are shown in Fig. 2 in the form of plots of the fringe amplitude as a function of the interferometer hour angle. (The interferometer hour angle (IHA) is defined as the hour angle of the source measured from the meridian of the equatorial projection of the baseline.) The location in the ( $u, v$ ) plane of each of the maxima and minima in the visibility function is indicated in Fig. 1.

The separation and direction of lines joining corresponding maxima and minima of the visibility function demonstrate the multiplicity of components and give the approximate extent of the source and the direction of elongation. In the inner part of the ( $u, v$ ) plane the spacing corresponds to a total separation of about  $0.006''$  between the outer major features; the somewhat closer spacing of the extrema on the longer baselines requires weak compact features separated by up to  $0.01''$ . The

\*The geographic location of the stations and the baseline lengths have been given in ref. 7.

\*\*A quartz oscillator was used to reduce the short term noise from the rubidium standard.

Fig. 1 Diurnal tracks for the six interferometers in the  $(u, v)$  plane. The units in  $u$  and  $v$  are in  $\lambda \times 10^6$ . Maxima and minima in the fringe visibility are shown by filled circles and crosses, respectively, except on one track (MPIR-HRAS), where the data are sparse. The line joining the principal maxima is shown dashed.

decrease in fringe amplitude along the line of the principal maximum (the line through the origin) shows that the size of the source along the minor axis is about  $0.0015''$ . As can be seen from Fig. 2, the maximum fringe amplitude on the three longer baselines is only  $\sim 10\%$  of the total flux density of  $58.4$  Jy, while on the shortest baseline the fringe visibility reaches  $90\%$ . Most of the emission therefore originates in components larger than  $0.001''$ . The rapid changes in fringe amplitude with hour angle observed on the trans-Atlantic baselines are real and the data have been confirmed by repeated observations.

A model describing the source brightness distribution was derived as follows: first, the overall extent and elongation of the source was determined by inspection of Fig. 2. Next, the brightness distribution was approximated by a model consisting of 10 elliptical Gaussian components. The parameters of each of these components were found by an iterative procedure which minimised the r.m.s. deviations between the observed data and the visibility function of the model. This preliminary model was then decomposed into a grid of point sources spaced  $0.0002''$  apart. The amplitude at each grid point was varied by another iterative procedure which further reduced the r.m.s. deviations between the observed visibility function and that of the model. Finally, the resulting grid was smoothed with a Gaussian beam having a FWHM of  $0.0004''$ . The resulting map of the radio structure of the NGC1275 nucleus is shown in Fig. 3, and the calculated fringe amplitudes of the unsmoothed model as a function of the IHA are shown in Fig. 2, together with the experimental data.

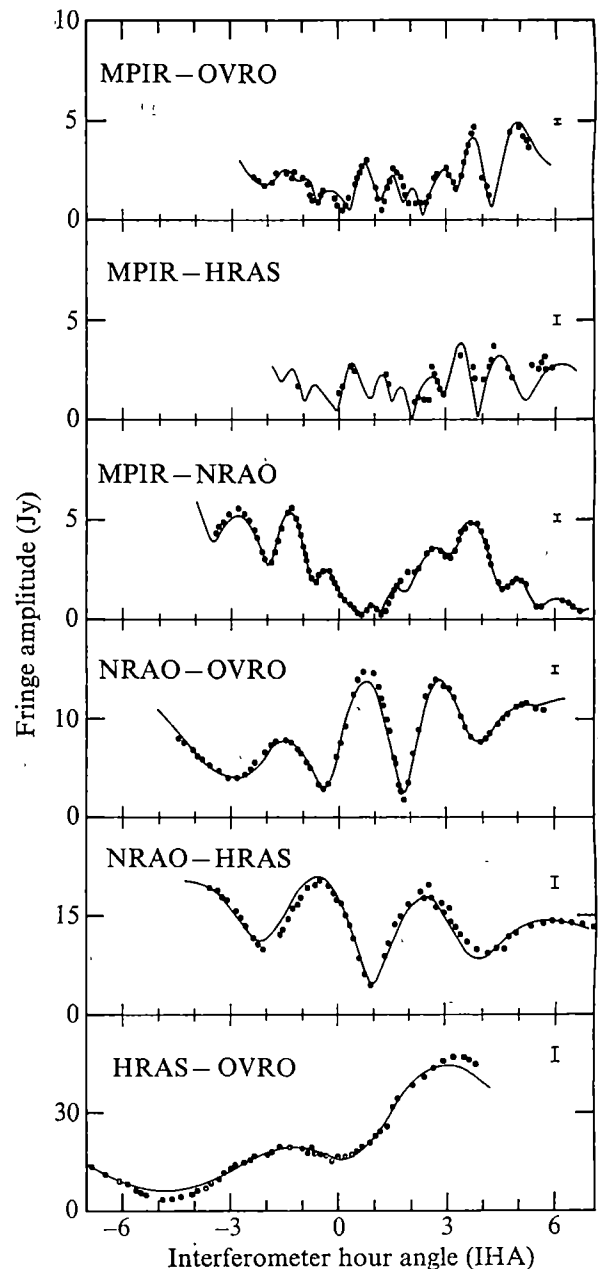

We emphasise that the map shown in Fig. 3 is based on fringe amplitudes alone, since we did not retain the phase information necessary to perform a Fourier inversion of the data. Models derived in this way are not unique; in particular, there is an ambiguity in the position angle of  $180^\circ$ . Also, the coverage of the  $(u, v)$  plane is incomplete, and even with phase information this would have led to sidelobes in the reconstructed map. To investigate the uniqueness of our model, we have used the iterative grid procedure starting from six-component and two-component models, rather than the ten components used to produce the map shown in Fig. 3. Each of these approaches gave very similar final maps. Moreover, four of the authors have independently derived a map using multi-component Gaussian models and different modelling procedures, and again these maps agree in their main features.

This is perhaps not surprising since the complexity of the

fringe visibility function, coupled with the restriction that the brightness should everywhere be positive, seems to provide constraints which facilitate the reconstruction of the main features of the brightness distribution even in the absence of phase data. It is always possible to find a more complex geometry which gives an even better fit, but the data do not justify more complex models. We believe, however, that the data do require a model of the complexity of that shown in Fig. 3. We note that the evidence for fine structure on a scale  $\lesssim 0.001''$  comes primarily from the trans-Atlantic baselines. A much simpler model, consisting of five Gaussian components, fits the data from the three shortest baselines adequately, and reproduces the trend of the data from the longer baselines with deviations of only a few Jy.

As a further comparison, we have convolved our map with

Fig. 2 The fringe amplitude as a function of IHA for the six interferometers. The experimental data are shown as filled circles. The experimental errors for each interferometer are indicated by error bars at the right hand side of each plot. These are the errors corresponding to the largest fringe amplitude observed; errors near the minima of the fringe visibility are smaller than the size of the plotted symbols. The computed fringe amplitudes for the model structure are shown as solid curves.

a fan beam to produce a one-dimensional strip scan along the major axis. We find that this agrees qualitatively with the one-dimensional brightness distribution which has been derived<sup>3</sup> from amplitude and phase-closure data obtained at 3.8 cm at epoch 1973.7.

### Nature of radio source

The major features of the radio nucleus of NGC1275 seen in Fig. 3 are the three areas of high brightness. The separation between the peaks of the two outer regions is  $0.006''$  and the overall extent along the major axis down to the 10% contour level is  $0.01''$ . The centres of the three major peaks lie nearly on a straight line in position angle  $-9^\circ$ . In this sense the structure is 'colinear' although there are clearly significant deviations from a simple linear structure. The size (FWHM) along the minor axis is  $\sim 0.0015''$ . The brightest feature is located near the centre of the source and has a peak brightness temperature of about  $10^{11}$  K on the smoothed map. Observations of still higher resolution will be required to study this compact region.

The redshift of NGC1275 is 0.018, corresponding to a distance of 110 Mpc ( $H = 50 \text{ km s}^{-1} \text{ Mpc}^{-1}$ ), so that  $0.001''$  is equivalent to a linear distance of 0.5 pc. The separation of the two major outer components is then 3 pc, and a significant part of the emission from the central component originates from a region smaller than 0.1 pc.

In Fig. 4 we have plotted the radio-frequency spectrum of the source 3C84 between 20 MHz and 100 GHz using the data taken from the literature as indicated. The spectrum can be broken down into three parts<sup>8,9</sup>, associated with structure on different angular scales:

(A) A high frequency spectral component associated with the radio structure discussed here. This component becomes self-absorbed below about 5 GHz. At 10.65 GHz the measured total flux density was 58.4 Jy. Extrapolation of the two components B and C indicates that they contribute about 1.5 Jy at 10.65 GHz and our model of component A accounts for all the remaining flux density.

(B) A decimetre wavelength spectral component which becomes self-absorbed below 500 MHz. Purcell (personal communication) has studied this component with the NRAO-HRAS-OVRO interferometer at 609 MHz. The structure is elongated at a position angle near  $0^\circ$ , and is probably double with a component separation of about  $0.05''$  (25 pc). The available data do not allow the relative positions of component A and the double source making up component B to be determined accurately. The centroids of the two components must, however, lie within a few arc seconds of each other.

(C) A component with a 'normal' power-law spectrum. This extended feature has been studied<sup>15</sup> with the Westerbork array at 1,420 MHz. It consists of a  $30''$  (15 kpc) source coincident with the galaxy and a larger,  $5'$  source (150 kpc), both of which are elongated roughly along position angle  $-10^\circ$ .

Each of the components A, B, and C is elongated in essentially the same direction. Moreover, the H $\alpha$  filaments, which extend<sup>16</sup> more than  $140''$  from the centre of the galaxy, also have their greatest extent in this direction. This suggests a common mechanism of alignment which is effective over linear scales ranging from a few pc in the dense nucleus of the galaxy to more than 100 kpc in intergalactic space.

The 150 kpc component must be at least  $5 \times 10^5$  yr old and is probably 10–100 times older. Component A, on the other hand, is probably not more than 20 yr old. Although the earliest observations<sup>17</sup> of the flux density of 3C84 at 10.7 GHz were made in 1966, measurements at 8 GHz (ref. 18) go back to 1960 at which time the flux density was only about 10 Jy. At the time of our measurements, however, the flux density at 8 GHz had increased to 55 Jy (Blankenship, personal communication), so that most of the present component A did not exist before 1960. Numerous observations at centimetre wavelengths since 1965 show that the flux density of component A increased in an approximately linear manner until

1973 and has remained roughly constant since that time (for example, refs 5, 19, 20).

Unfortunately, we have high resolution observations beginning only in 1972, so that we cannot trace the development of component A in detail. Previous interferometer data<sup>5</sup> taken at 10.7 GHz with an angular resolution of about  $0.001''$ , made with the NRAO-HRAS-OVRO antennae at the epochs 1972 April, 1972 October and 1973 March, show that the maxima and minima in the fringe visibility have remained at nearly constant positions in the  $(u,v)$  plane, while the amplitudes of the extrema have varied considerably over this time.

Fig. 3 The structure of the radio nucleus of NGC1275, derived as described in the text. Contours are given in 10% intervals of the maximum brightness down to the 10% level; the 5 and 2.5% levels are shown dashed. The scale in the two coordinates is indicated by the  $0.001''$  bar in the lower right corner. North is at the top and East at the left, but there is a  $180^\circ$  ambiguity in the orientation of the map (see text)

This implies that the overall dimensions of the source and the relative locations of the three bright condensations have not changed significantly, but their intensity and/or size has varied during this time. Thus the nucleus of NGC1275 seems to contain three apparently stationary centres, separated by

**Fig. 4** The radio spectrum of NGC1275. Above 1 GHz, the epoch is that of the present measurements (1974.5). Total flux density data below 1.65 GHz are taken from Ryle and Windram (ref. 8); at 1.65 GHz from unpublished data obtained by Webber, Denoyer and Swenson; above this frequency from unpublished measurements made by the authors and A. Niell. The separation into spectral components A (—), B (---) and C (· · ·) is based on interferometer data at 408 MHz and 1.4 GHz (ref. 10); 448 MHz (ref. 11); 609 MHz (Purcell, personal communication); 1.4, 2.7 and 5 GHz (ref. 12); 1.65 GHz (ref. 13) and 2.3 GHz (ref. 14, and unpublished data). In making the separation, we have assumed that components B and C have not varied during the period 1969 to 1974.

a few pc and lying nearly along a straight line; at least one of these centres has been active in the past three years. This is in contrast with the quasar 3C273 and the radio galaxy 3C120, where the location of the extrema changes rapidly<sup>6</sup>, suggesting rapid movements of the radiating components.

Repeated observations with multi-element intercontinental interferometer systems are necessary to study the details of the time variations in the nucleus of NGC1275. This would give unprecedented insight into the powerful energy source located in the nuclei of galaxies and specifically into the mechanism responsible for the origin of extragalactic radio sources.

We thank B. Rayhrer and J. Burch for their support in the operation of the NRAO Mk II VLB processor. The NRAO is operated by Associated Universities, Inc., under contract with the NSF; Owens Valley Radio Observatory and Harvard Radio Astronomy Station are both supported by the NSF; J.R. received an NSF predoctoral fellowship.

# The structure of the protein disk of tobacco mosaic virus to 5 Å resolution

J. N. Champness, A. C. Bloomer, G. Bricogne, P. J. G. Butler & A. Klug

MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK

*An electron density map of the TMV disk at 5 Å resolution has been obtained using isomorphous replacement and non-crystallographic symmetry. The polypeptide chain can be traced with little ambiguity. The axial contacts between protein subunits are unlike those in the virus, the disk being a more open structure apparently designed for rapid interaction with the RNA.*

THE disk of tobacco mosaic virus (TMV) protein is crucial in the assembly of the virus from its RNA and protein. It is composed of two rings each containing 17 protein subunits<sup>1</sup>, both layers facing the same way<sup>2</sup>. The disk has long been known as one of the polymorphic forms of TMV protein<sup>3</sup>, but it was only recently shown to be the dominant aggregate at neutral pH and moderate ionic strength<sup>4</sup>, essential for nucleation of the virus assembly, and to contribute to the rapid elongation of the nucleoprotein rod<sup>5,6</sup>. The interaction of the disk with a special sequence on the RNA also provides a mechanism for recognition by the protein of its homologous RNA<sup>5</sup>.

The X-ray diffraction study of the disk was begun before its relevance to virus assembly had been established, when crystals were obtained during systematic attempts to crystallise small aggregates of the subunits<sup>1</sup>. These earlier X-ray studies, leading to a low resolution electron density map, have been described<sup>7–9</sup>. Because of the large size of the unit cell, which has a whole disk of molecular weight 600,000 as its asymmetric unit, the extension to high resolution posed a formidable technical problem, which was overcome only by the development in this laboratory of an automated camera, together with a computer-linked densitometer and associated computer programs for processing the hundreds of thousands of X-ray intensities involved<sup>10–12</sup>. Here we describe the extension of the X-ray work to 5 Å resolution.

The structure has been solved by the method of isomorphous replacement. Only two heavy-atom derivatives were used, but good phases were nevertheless obtained by using the 17-fold rotational symmetry of the disk; this non-crystallographic axis gives rise to redundant information in the X-ray data which can be exploited in phase determination. The validity of the final electron density map is demonstrated by the striking similarity between the two

rings of the disk, which are crystallographically independent and whose similarity was not assumed at any stage. The map is sufficiently clear for the course of the polypeptide chain to be traced with little ambiguity.

### X-ray data collection

The preparation and crystallisation of the virus protein has been described by Leberman *et al.*<sup>7</sup>. The crystals are orthorhombic, space group  $P2_22_1$ , with unit cell  $a=228$  Å,  $b=224$  Å and  $c=174$  Å. The disks stack in pairs related by the crystal dyad<sup>8</sup> with their 17-fold rotation axis approximately parallel to  $c$ .

There are 39,000 unique reflections to 5 Å, and a complete set of data, allowing for scaling overlaps, requires the recording of about 200,000 reflections. X-ray intensities were first collected from crystals of the native protein and of a covalently-bound methylmercury derivative<sup>7</sup>. Subsequently, to check and improve the phasing, data were also collected from a  $(AuCl)_2^-$  derivative, but this proved to have low occupancy.

X-ray photographs were taken on an Arndt-Wonacott oscillation camera<sup>10</sup> using small contiguous rotations, about the  $b$  axis, of approximately  $1^\circ$  per film pack. The total rotation angle required was  $90^\circ$ , necessitating several crystals for each set of data. Reflections occurring at the

Table 1 Statistics of data collection to 5 Å

	Native	Mercury	Gold
Total reflections measured	181,000	198,000	118,000
No. of split reflections	57,000	73,000	42,000
No. of independent reflections	38,800	39,100	37,600
$R_{\text{sym}} = \sum_i  \bar{F}_i - F_i  / \sum_i \bar{F}_i$	0.14	0.10	0.13
$R_{\text{sym}}$ , 50% strongest reflections	0.08	0.06	0.07
Mean isomorphous difference $\langle  F_{\text{nat}} - F_{\text{der}}  \rangle / \langle F_{\text{der}} \rangle$	—	0.30	0.19

The films were scaled together by means of symmetry-related reflections recorded on different films and a symmetry  $R$  factor was computed for each compiled set of data. Split reflections could not be used for scaling but were included in the statistics. Their exclusion did not significantly improve the  $R$  factor.

boundaries of contiguous rotations were split between consecutive films, and such data were assimilated by adding the integrated intensities of the separate parts from each film<sup>10</sup>. Films were measured on a flat-bed scanner (J. F. W. Mallett, T. H. Gossling, A. R. Faruqi, and J.N.C., unpublished) which combines the positional accuracy of a mechanical stage<sup>11</sup> with the speed of a flying-spot densitometer<sup>12</sup>. The data quality (Table 1) is poor by small protein standards because of the high proportion of weak reflections and the limited exposures, although these were already several hours per degree of oscillation on a rotating-anode X-ray tube. We accepted this lower standard, however, because of the expectation, which was later justified, that the 17-fold redundancy implicit in the data would compensate for this. Better data were obtained for the mercury derivative, for which larger crystals and longer exposures were used.

### Phase determination

Phases were obtained by a combination<sup>13</sup> of isomorphous replacement and non-crystallographic symmetry<sup>13,14</sup>. The mercury positions found by Gilbert and Klug<sup>9</sup> from the centrosymmetric zones were refined using 20,000 selected reflections. The refined positions were used both to locate the non-crystallographic 17-fold axis precisely and to calculate a single isomorphous map. The asymmetric unit was isolated, averaged 17-fold, and the averaged structure replaced in the unit cell. The averaged map was then used to compute a set of structure factors ( $F_{\text{calc}}$ ). Treating the map

Table 2 Progress of the phase determinations starting from single (SIR) and double (DIR) isomorphous replacement

	SIR			DIR			
Cycle	0	1	2	0	1	2	3
$R$ factor after averaging		0.38	0.35		0.39	0.31	0.28
Figure of merit	0.48	0.67	0.68	0.60	0.74	0.77	0.78
Mean phase change from last cycle		34.5°	3.4°		24.7°	6.5°	2.9°

$R = \langle |F_{\text{obs}} - F_{\text{calc}}| \rangle / \langle F_{\text{obs}} \rangle$ , where  $F_{\text{calc}}$  is the structure factor computed from the average map.

as the known part of a total structure, phase-probability distributions were computed from the  $F_{\text{calc}}$  using Sim's formula<sup>15</sup>. The sharpness of the distributions depends on the agreement between the measured amplitudes ( $F_{\text{obs}}$ ) and the  $F_{\text{calc}}$  over the complete set of data. These distributions were combined multiplicatively with those obtained from isomorphous replacement to calculate new best phases and figures of merit. Attaching these to the  $F_{\text{obs}}$ , another map was calculated, enabling the cycle of averaging and phase-recombination to be repeated.

After only two or three cycles, the mean phase change per cycle was as little as  $3^\circ$ . Phases from the final cycle were used to locate the heavy atoms in the gold derivative, and ultimately the above procedure was repeated starting from double isomorphous phases. The course of each phase determination is summarised in Table 2. The final mean figure of merit was higher for the determination starting with the double isomorphous phases (0.78) than for that starting with the single (0.68). Nevertheless, the final maps in each case were of comparable quality, showing that the use of the non-crystallographic symmetry was of greater value than the second isomorphous derivative. The heavy-atom parameters for the two derivatives are given in Table 3. The hand was determined from the anomalous differences in the derivative data.

### The electron density map and its interpretation

The map in Fig. 1 is the 17-fold averaged structure and is plotted on sections perpendicular to the 17-fold axis. The figure shows approximately  $4\pi/17$  rad of the disk (two subunits wide) sliced into four thick composite sections, A1, A2, B1 and B2, each about half a layer deep. The two layers are denoted A and B, where A is closer to the crystal dyad, and each ring is divided into two parts, 1 and 2, to give the four sections (Fig. 2). Each layer contains two slewed rods of density (LS, RS) per subunit in the upper half and two radially oriented rods (LR, RR) underneath

Table 3 Heavy atom parameters

	Mercury		Gold	
	Ring A	Ring B	Ring A	Ring B
Relative occupancy	58	58	23	14
Radius in Å	59.2	58.9	72.5	70.1
Height above dyad in Å	12.1	38.8	3.5	28.9
Azimuth ( $\phi$ )	4.1°	8.0°	-0.6°	3.2°
Phasing power $\langle f_H \text{ calc} \rangle / \langle E \rangle$	2.78		1.10	

$f_H \text{ calc}$ , Calculated heavy atom structure factor.

$E$ , lack of closure error.

The 34 sites for each derivative were refined against the phases calculated by combining the probability distributions for the DIR phases (in which the weight of the gold contribution had been doubled) with those resulting from two cycles of averaging and recombination of the SIR phases. This procedure was necessary to prevent the mercury derivatives from completely dominating the DIR phase calculation and refinement. The Table gives the 17-fold averages of the parameters refined for individual atoms. None of the mercury positions differed by more than 0.3 Å from those corresponding to perfect symmetry. R385

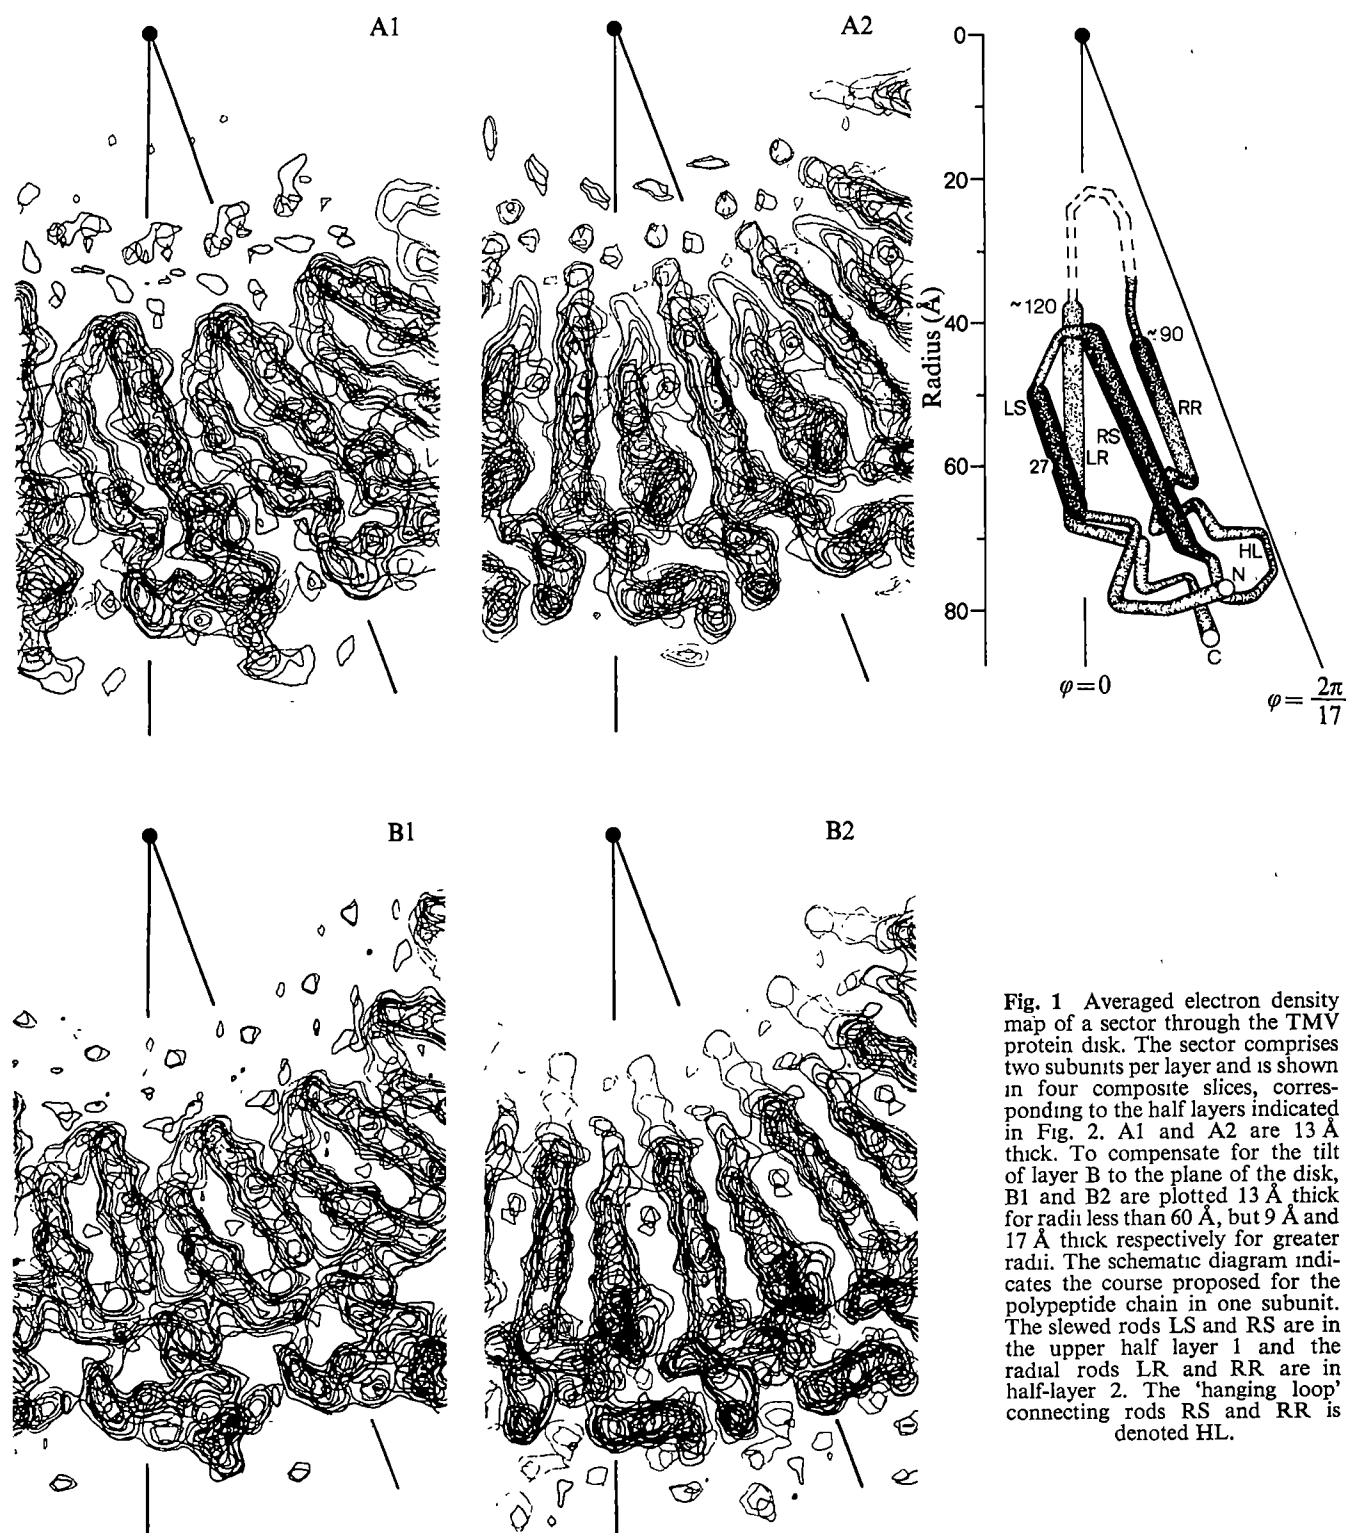

Fig. 1 Averaged electron density map of a sector through the TMV protein disk. The sector comprises two subunits per layer and is shown in four composite slices, corresponding to the half layers indicated in Fig. 2. A1 and A2 are 13 Å thick. To compensate for the tilt of layer B to the plane of the disk, B1 and B2 are plotted 13 Å thick for radii less than 60 Å, but 9 Å and 17 Å thick respectively for greater radii. The schematic diagram indicates the course proposed for the polypeptide chain in one subunit. The slewed rods LS and RS are in the upper half layer 1 and the radial rods LR and RR are in half-layer 2. The 'hanging loop' connecting rods RS and RR is denoted HL.

The structural similarity between the two crystallographically independent layers of subunits in the disk is indicative of the high quality of the phase determination. The map confirms earlier results that the disk is polar and has a pairing interaction between layers at high radius<sup>2,9</sup>, as is clearly seen in side view (Fig. 2).

The precise relationship between the two layers is most easily found by comparing features common to each layer in cylindrical sections of the map (for example Fig. 3). The two are related by an azimuthal shift of about 4°, constant for all radii, whereas the axial separation of common features decreases linearly from 30 Å at low radius to 22.5 Å

at high radius, compared with a constant separation of 23 Å in the virus helix. At the present resolution, therefore, the interaction between layers does not involve any appreciable distortion of the subunits, but rather a bodily tilting by 10° of the subunits in one ring with respect to the other. The large gap between the two layers at a radius of 40 Å evidently allows the initial accommodation of the RNA, since the latter is at this position in the virus<sup>16</sup>.

The rods of density between radii 40 Å and 70 Å, are strongly suggestive of  $\alpha$ -helices. They are approximately equispaced, 10 Å apart, within each layer so that there is little distinction between inter- and intramolecular contacts

in this region. The rods make angles of 10–20° with each other in a left-handed relationship, as is appropriate for right-handed  $\alpha$ -helices. The two slewed rods are connected at 40 Å radius, showing that they belong to the same subunit. At high radius there is a 'hanging loop' connecting the right slewed rod (RS) to the right radial rod (RR) beneath it. The bottom of this loop is in close contact with the left radial rod (LR) of the neighbouring subunit. The simplicity of the arrangement of four dense rods extending from 45 Å to 65 Å contrasts sharply with the highly contorted density towards the outside of the molecule. Interpretation in this region is difficult but is helped by having two independent copies of the subunit, one in each layer. The subunit boundaries in the axial direction are particularly easy to locate because of the clear separation both between disks and within a disk. The chain tracing finally chosen is shown in Fig. 1 together with the electron density map. The subunit delineated is compact, tapering at low radius, broadening and bending azimuthally at high radius.

One disappointing feature of the map is the lack of density at radii below 40 Å; in the helical aggregate of TMV protein<sup>17</sup> 20% of the density lies in this region. The radial rods in our map both peter out at 40 Å radius, suggesting that they are connected at lower radii but that this region is disordered in the disk. The absence of density in the map cannot be accounted for by chain cleavage, since sodium dodecyl sulphate (SDS) gels of old crystals show that virtually all the protein is of the correct size. A second possibility, that the 17-fold symmetry holds only at radii higher than 40 Å so that averaging the map smears out the true structure at lower radii, was discounted on inspection of the unaveraged map which shows no extra density at low radius.

A comparison of our map with that of the virus obtained in Heidelberg by Holmes *et al.*<sup>18</sup> reveals reasonable agreement in the gross features. The connections between the helical regions in our protein subunit, however, do not agree with those derived from their lower resolution map. Both maps show four rods of density at intermediate radii, of which the lower two are more or less radial and the upper two are both slewed to the right. We identify our left and right radial rods with ribbons 3 and 2 respectively of the virus map, and our left- and right-slew rods with ribbons 1\* (of the next subunit) and 4, but the connectivity is quite different. Starting from the N-terminus, our order is LS, RS, RR, LR, corresponding to 1\*, 4, 2, 3 in the Heidelberg notation. The differences in interpretation arise because the clear connection between our slewed rods at 40 Å radius is missing in the virus map and because our map shows no connecting density between the radial rods at 70 Å radius in contrast to the strong loop between ribbons 2 and 3 in the virus map. The radial rods in our map pass continuously into the density at high radius, whereas in the virus map the latter forms an isolated 'island'.

### Folding of the polypeptide chain

The most reliable information for correlating the course of the polypeptide chain (Fig. 1) with the sequence of 158 amino acid residues comes from the location of residues 1, 27, 115 and 139 labelled by heavy atoms in the virus<sup>18,19</sup> and of residue 27 in the disk. There are also indirect data, reviewed by Durham and Butler<sup>20</sup>, mainly concerning the accessibility of residues and regions of conserved sequence. The conservation of positively charged residues in all known strains and mutants at positions 41, 90, 92 and 113 suggests the proximity of these residues in the virus to the sugar-phosphate backbone of the RNA at 40 Å radius.

Arginine 41 can be assigned to the neighbourhood of the bend at 40 Å connecting the LS and RS rods, since cysteine 27 is located by the mercury atom at a radius of

60 Å close to the LS rod (Fig. 1), while the N-terminus is at high radius<sup>19</sup>. The other conserved arginines are therefore probably situated on the radial rods near the RNA radius. This is consistent with putting the stretch of sequence 90–120 at still lower radii, for which there is indirect evidence<sup>21</sup>, and thus assigning this region to the invisible chain connecting the two radial rods. The interaction of RNA with protein would then involve arginine 41 of the subunit below the RNA and arginines 90, 92 and 113 of the subunit above it.

The availability of the C-terminal residue to carboxypeptidase digestion in the intact virus<sup>21</sup> suggests that this is on the outside, at high radius. Residue 139 can be located approximately between the outer continuations of the radial rods by relating the coordinates of the dimercure acetic acid and methylmercury sites in the virus<sup>18</sup> to the methylmercury site in the disk. We choose the left-hand rod for 139, and thus the right-hand rod for 90, as this gives a more plausible connection of the remaining density than does the reverse. The left-hand radial rod is connected to the C-terminus at high radius through density in the lower half of the subunit.

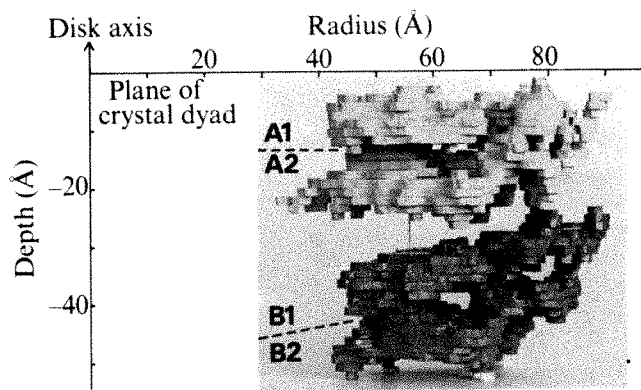

Fig. 2 Side view of a balsa-wood model of two subunits in each layer of the protein disk. The layers interact closely only at high radius, subunits in ring B being tilted away from subunits in ring A at low radius.

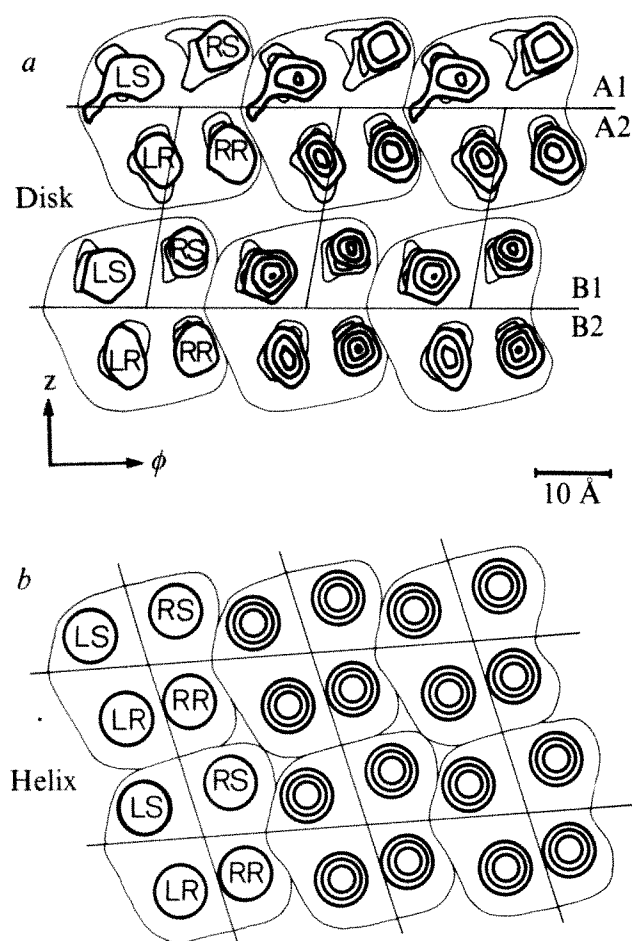

Our interpretation of the map allows the rods to be in the  $\alpha$ -helical configuration over most of their length, and two stretches of sequence rich in hydrophobic residues (74–87 and 119–133) are assigned within the radial rods RR and LR respectively. Parts of the RS and RR rods, however, may be more extended than a regular  $\alpha$ -helix so that the combined length of the two rods and the 'hanging loop' connecting them can be spanned by residues 41–90. The chain tracing proposed here is not the only one conceivable, but accords best with the electron density map. The most uncertain feature concerns a four-way contact at 70 Å radius involving the RS and RR rods and the connecting 'hanging loop'. The direction of the sequence through this loop may be the reverse of that proposed here.

### Subunit packing

The subunits within a layer are tightly packed, the principal contacts being those associated with the  $\alpha$ -helical packing in the region of radii 40–70 Å. There are only two main contacts between layers and these can be seen in Fig. 2 at radii 65 and 80 Å. In the virus, however, lateral and axial contacts between subunits seem to be equally close.

The surface lattices of the disk structure and the virus helix are compared in Fig. 3. The 16-fold helix family in

the virus has a one-third subunit displacement to the left<sup>22</sup> between turns, whereas the two rings of the disk have a relative azimuthal displacement of about one-fifth subunit to the right. Thus the geometry of axial contacts between the two rings of the disk is quite different from that between successive turns of the virus helix. Figure 3a shows a cylindrical section of the electron density map of the

**Fig. 3** Packing of subunits and  $\alpha$ -helical rods in the protein disk and the virus. *a*, Superposed cylindrical sections of the electron density map of the disk at radii 57, 58.5 and 60 Å. The subunit outline is shown. *b*, Schematic diagram of the same subunits arranged in the surface lattice of the virus helix.

disk at a radius of about 58 Å illustrating the packing of the  $\alpha$ -helical rods. The rods are well packed laterally within a layer of the disk, but there is only one close contact between layers. If, however, we generate the packing in the virus in this region by applying the appropriate displacement to one layer such that the surface net of the disk is converted to that of the virus (Fig. 3b), the layers now fit snugly. Further contacts are made giving a continuous two-dimensional array of close-packed rods.

### Implications for virus assembly

The disk has a primary function in both the initiation of the virus structure and its subsequent elongation<sup>5,6</sup> and the structure we have found suggests how this might occur. The disk is not just a simple piece of virus-like structure without the RNA, but it is an intermediate assembly of protein molecules designed for incorporation of the RNA before subsequent transformation to the final helical

arrangement. The contacts between layers of the disk are few, and at the RNA radius the subunits of the disk are about 7 Å further apart axially than they are in the virus. The two layers of the disk thus have the appearance (Fig. 2) of an open pair of 'jaws', awaiting the incorporation of the RNA. We would expect initiation of assembly to involve the reaction of a single disk with the RNA, as has been found to be the case (ref. 6, p. 343).

As the RNA binds to the disk at 40 Å radius, the inner disordered region presumably adopts the virus configuration, the bonds between layers at higher radius being broken as the new bonds characteristic of the virus configuration (compare with Fig. 3) are formed. The disk would presumably dislocate to a helical segment at some point in this process, the RNA beginning its second turn. Another disk could then attach to start the regime of rod elongation. There is no need to postulate distinct mechanisms for initiation and elongation; the flexibility of the chain at low radius would facilitate intercalation of the RNA between the protein subunits, thus resolving the paradox of elongation from a two-layered structure—the disk<sup>22</sup>.

The disorder of the protein in the disk at low radius may be symptomatic of a somewhat nonspecific chain configuration at low radii in the virus, where a unique protein sequence has to accommodate a variety of RNA base triplets in different subunits. This disorder in the disk suggests that the protein does not carry three preformed sites, of the lock-and-key kind, to house the RNA, but rather that the sites are created during the interaction between them. Nevertheless, there must be sufficient stereospecificity in the disk to recognise the special initiation sequence of the RNA, although not all successive bases of this sequence need be involved.

Further details of the interactions between subunits and between protein and RNA, together with confirmation of the folding we propose for the protein subunit must await a 2.8 Å resolution map, the data collection for which is now in progress.

We thank R. Staden, C. Villa and Mrs C. Harley for assistance and Dr T. C. C. Tao for help in the search for isomorphous derivatives. We thank the Heidelberg group for supplying us with a copy of their virus map. Early experiments showing the feasibility of the averaging computations were done during a CECAM Workshop organised in Orsay by Dr C. Moser. We thank the Cambridge University Computer Laboratory for making special arrangements for the final computations.

# letters to nature

## Pulsar atmospheric current loops

THE basic difficulty with the theories of pulsar radiation is that there is as yet no self-consistent model of the large scale structure of the plasma atmosphere of the pulsar<sup>1, 2</sup>. The lack of such a model is perhaps most strikingly exemplified by the fact that there is no consistent explanation of how an aligned rotating magnetised neutron star can maintain a net zero current from its surface—that is, how either a finite current loop in its atmosphere, or an 'infinite' loop to the nebula, is established consistent with the space charge and the electromagnetic fields<sup>3, 4</sup>. This letter will be limited to a discussion of how current loops are established when the rotational and magnetic axes are aligned.

To avoid the extreme conditions which may exist in real pulsars, we will use a gedanken device to tackle the problem. The rotational state of the star will be obtained by beginning with a magnetised star in a vacuum, and adiabatically increasing its angular velocity  $\Omega(t)$ . In this way the various physical complications can be introduced in a systematic manner—ordered according to the value of  $\Omega$ . Our concern is essentially limited to the lowest order influence of  $\Omega$ , which requires a resolution of the current loop problem.

The rotation of a conducting star about its dipole magnetic field axis, induces an electric field which must satisfy the boundary condition

$$E_\theta(r = R, \theta) = -(Q/2R^2) \sin 2\theta \quad (1)$$

where  $Q = (\Omega \cdot \mathbf{B}_0)R^3/c$ , and  $\mathbf{B}_0$  is the polar magnetic field strength. Goldreich and Julian<sup>3</sup> recognised that for real pulsars this yields very large values of  $\mathbf{E} \cdot \mathbf{B}$ , causing large currents from the star, hence invalidating the vacuum assumption. They then made the assumption that  $\mathbf{E} \cdot \mathbf{B} \approx 0$  which, together with equation (1), leads to a corotational atmosphere and their paradoxical result concerning 'proton' currents passing through

negatively charged regions<sup>4</sup>. They also introduced the assumption of a group of open magnetic surfaces, along which current flows to the nebula. These basic assumptions, which have been widely accepted in the literature, are totally different from the model proposed here.

If we take  $\Omega$  to be small (hence small  $Q$ ), the Goldreich and Julian vacuum field would initially draw only electrons from the star, primarily from the polar regions. This would give rise to a stellar charge  $q_s = \epsilon Q$ . To the degree that the electrons move to large distances, thus producing little space charge, the electrostatic potential which satisfies equation (1) is

$$\Phi = \frac{Q}{r} \left[ \epsilon - \frac{1}{6} \left( \frac{R}{r} \right)^2 (3 \cos^2 \theta - 1) \right] \quad (2)$$

and

$$\mathbf{E} \cdot \mathbf{B} = \frac{QB_0}{R} \left[ \epsilon - \left( \frac{R}{r} \right)^2 \cos^2 \theta \right] \left( \frac{R}{r} \right)^5 \cos \theta \quad (3)$$

The effect of the stellar charge is to slow down and eventually stop any net electron escape from the star. This will occur approximately when the polar potential equals the nebular potential at some nebular distance ( $r = R_N$ ). For  $R_N \approx \infty$ ,  $\Phi(R, \theta = 0) = \Phi(\infty, \theta = 0)$  if  $\epsilon = 1/3$ . This net stellar charge,  $q_s = Q/3$ , does not stop electron emission from the polar region, as can be seen from equation (3). The problem therefore remains to determine the flow of these electrons which can no longer escape into the nebula. The details of this plasma flow is not particularly simple, and will be discussed in a later publication. To give a qualitative (and simplistic) picture, it is of some help to introduce regions in which the plasma flow is dominated by either the electric or magnetic field:

$$\begin{aligned} \text{magnetic flow region (MFR): } |\mathbf{E} \times \mathbf{B}| &> E^2 \\ \text{electric flow region (EFR): } |\mathbf{E} \times \mathbf{B}| &> B^2 \end{aligned} \quad (4)$$

In these regions the average acceleration of the particles is along  $\mathbf{B}$  (in the MFR) or  $\mathbf{E}$  (in the EFR), and in an intermediate direction in the region near  $\mathbf{E} = \mathbf{B}$ . These regions are illustrated in Fig. 1 for the dipole  $\mathbf{B}$  field, and  $\mathbf{E}$  obtained from equation (2), with  $\epsilon = 1/3$ . The (toroidal drift velocity/ $c$ )  $\equiv \beta$ , given in ref. 5 by  $\beta/(1 + \beta^2) = (\mathbf{E} \times \mathbf{B})/(E^2 + B^2)$ , is not corotational and generally  $\beta \neq 1$  any place on a field line. The essential point to note is, however, the flow across magnetic surfaces in the EFR (a point which apparently has not been noted in the force-free approximation).

If electrons start from rest at  $(R, \theta_0)$  and move out along the dipole field lines  $r = R(\sin \theta / \sin \theta_0)^2$  (Fig. 1), where the field line is labelled by its stellar surface angle  $\theta_0$ , they would be energetically able only to reach a point  $(r^*(\theta_0), \theta^*(\theta_0))$  given by

$$\Phi(r^*, \theta^*) \equiv \Phi(R(\sin \theta^* / \sin \theta_0)^2, \theta^*) = \Phi(R, \theta_0) \quad (5)$$

In this case, once arriving at  $\theta^*(\theta_0)$  they would be reflected and return to the star. If, however,  $\theta^*(\theta_0)$  falls in the EFR, the electron will accelerate across magnetic surfaces to surfaces with larger values of  $\theta_0$  (lower electrostatic energy). [Note that this fixation on the EFR is a dynamic simplification, which neglects some 'shorting' across magnetic surfaces which begins when  $E > B$  (Fig. 1). The present concern is conceptual rather than

Fig. 1 Plasma flow regions: acceleration along  $\mathbf{B}$  for the MFR (region I), along  $\mathbf{E}$  for the EFR (region II), or in intermediate directions ( $E \approx B$ ). The star is at the origin. The solid lines follow dipole lines:  $r = R(\sin \theta / \sin \theta_0)^2$ .

Fig. 2 Schematic of the primary electron current loop which crosses magnetic surfaces in the EFR. Inner and outer polar angles ( $\theta_p^i$ ,  $\theta_p^o$ ) at the stellar surface are defined by the indicated magnetic surfaces.

analytic.] This, then, distinguishes three groups of magnetic surfaces: (a) those such that  $(r^*(\theta_0), \theta^*(\theta_0))$  lies in the EFR; (b) those surfaces which enter the EFR, but for which  $(r^*, \theta^*)$  is not in EFR; (c) those surfaces which do not enter the EFR. The stellar surface angle which separates the group (a-b) and (b-c) define an inner polar angle ( $\theta_p^i$ ) and an outer polar angle ( $\theta_p^o$ ) respectively. These features are illustrated in Fig. 2.

This model predicts that the electrons which flow out along the magnetic surfaces  $\theta_0 < \theta_p^i$  will enter a region (for example the EFR) where they cross magnetic surfaces to surfaces with larger  $\theta_0$ . In the process they will leave the electric-dominated region and then follow their new magnetic surface back to the star—forming the required current loop. The return flow of electrons will be largely restricted to the stellar annulus  $\theta_p^o > \theta_0 > \theta_p^i$ , the larger angle corresponding to the outermost surface to enter the EFR. An examination of the potential energy obtained from equation (2) shows that this flow pattern is consistent with the fields. This flow is schematically illustrated in Fig. 2. It will be noted that this current loop does not extend to the nebula, and does not represent any particle loss from the star (in contrast with large particle losses assumed in many pulsar models).

The present results are only valid to lowest order in  $\Omega$ . The use, however, of an adiabatically increasing  $\Omega(t)$  not only solves the immediate problem, but also gives a number of interesting side-features. The simple current diagram in Fig. 2 in reality consists of a 'plume' or 'fountain' particle flow formation, which cannot be described by simple hydrodynamic equations, and is quite likely unstable. Moreover, equation (2) exhibits a saddle-point potential energy minimum above the poles, which can naturally account for a stationary plasma atmosphere. The gedanken approach shows that this atmosphere, while requiring more stellar electrons, will not change the net star-plus-atmospheric charge, and thus the long range Coulomb force on which the present results rest. These features of a more complete pulsar atmospheric model will be published in the near future.

Finally it should be noted that the details of our results will be significantly changed if the rotational and magnetic axes are not aligned. This is clear from the spatial scale shown in Fig. 1. The analysis of the non-aligned case will be presented in a separate paper.

## An interstellar H<sub>2</sub> indicator in direction of the Crab Nebula

MOLECULAR hydrogen is very stable at low temperatures, and is therefore likely to be found in large quantities within interstellar dark clouds which are not penetrated by ultraviolet radiation (which destroys molecular bonds).

A case for a high concentration of H<sub>2</sub> in the interstellar medium can be made on the observed distribution of the galactic  $\gamma$ -ray emission<sup>1,2</sup>, but available information is still rather scanty as direct evidence of its presence comes only from regions which are very close to the Earth. For regions further out than 1 kpc, the experimental evidence is only indirect—obtained from CO microwave emission.

We have studied the shape of the low energy spectrum of galactic X-ray sources detectable on Earth. In the energy range 0.1–1 keV the continuous absorption by H<sub>2</sub> is intense. It adds to that produced by other components of the interstellar medium and affects the depth of the absorption edges of elements such as oxygen, neon and others. The oxygen feature at 0.532 keV is very prominent and allows a sensitive probe of the H<sub>2</sub> density between the X-ray source and the observer. We therefore calculated how such features in the low energy X-ray spectrum of the Crab Nebula would be affected by the interstellar abundance of molecular hydrogen.

H<sub>2</sub> between us and the Crab would not affect the propagation of the 21 cm radiation<sup>3</sup>, but we find that it would absorb X-rays. This accounts for a factor of 2 in the difference between X- and radio-estimations of the column density of the interstellar medium in this direction. Indeed, the higher X-ray column density cannot be explained by interstellar grains or by any anomalous abundance of the usual components of interstellar matter, except on very specific models which lack any experimental support<sup>4-6</sup>.

We made the following assumptions in our calculation: first the X-ray energy spectrum of the Crab Nebula in absence of absorption follows a power law

$$N(E)dE = KE^{-\gamma}dE$$

of constant spectral index  $\gamma$ .

Extrapolation to low energy of the spectrum measured above a few keV, where absorption is negligible, gives  $\gamma = 2.0$

Fig. 1 The X-ray energy spectrum of the Crab Nebula modified by interstellar absorption as seen with infinite resolution,  $\Delta E = 0$ , (a), and finite resolution,  $\Delta E = 150$  eV, (b), for different values of H<sub>2</sub> abundance. — — —,  $R = 0$ ; ———,  $R = 0.5$ .

**Table 1** Depth  $D$  of the oxygen absorption edge as a function of the  $H_2$  abundance  $R$ 

$R$	$D(R)/D(0)$
0	1
$5 \times 10^{-3}$	0.996
$10^{-2}$	0.980
$3 \times 10^{-2}$	0.948
$10^{-1}$	0.856
$3 \times 10^{-1}$	0.628
$5 \times 10^{-1}$	0.460
$7 \times 10^{-1}$	0.337

(refs 4, 5, 7). Second, the column density of atomic hydrogen is  $2.0 \times 10^{21}$  atoms  $\text{cm}^{-2}$  compatible with radio measurements at 21  $\text{cm}^8$ . Third, except for molecular hydrogen, the composition of the interstellar medium is standard. The absorption cross sections and abundances computed by Brown and Gould<sup>9</sup> have been adopted, and fourth, in the energy range of interest the absorption cross section of  $H_2$  has the form

$$\sigma_{H_2}(E) = 1.84 \times 10^{-22} E^{-3.3} \text{ cm}^2$$

Results of the calculations are presented in Fig. 1 and Table 1. Figure 1a shows the expected Crab Nebula low energy X-ray spectrum assuming  $R = 0.0$  or  $R = 0.5$  (where  $R = 2N_{H_2}/N_H$ ,  $N_{H_2}$  and  $N_H$  being respectively the densities of molecular and atomic hydrogen) and infinite resolution, ( $\Delta E = 0$ ). When  $H_2$  is present in the interstellar medium the depth of the absorption edges decreases. Table 1 gives, for various  $H_2$  abundances, the depth of the oxygen feature divided by the depth of the feature when  $R = 0$ . Figure 1b gives the same spectra as Fig. 1a calculated under the hypothesis that the best energy resolution now available at 0.5 keV is used,  $\Delta E = 150$  eV. The neon edge at 0.874 keV practically disappears. The oxygen absorption edge, indicated by a bump in the smooth trend of the spectrum, is now the only feature which stays

**Table 2** Height  $H$  of the oxygen bump in units of  $h\sigma$ , (see text), as a function of the  $H_2$  abundance  $R$ 

$R$	$H/h\sigma \text{ (cm}^2 \text{ s)}^{1/2}$
0	1.47
$10^{-2}$	1.46
$3 \times 10^{-2}$	1.44
$10^{-1}$	1.36
$3 \times 10^{-1}$	1.17
$5 \times 10^{-1}$	1
$6 \times 10^{-1}$	0.92

visible. To detect it in an experiment carried out with a detector of area  $A$ , efficiency  $\eta$  and energy resolution  $\Delta E$ , the Crab must be observed for such a long time  $t$  that the bump stands up by at least  $3\sigma$  above the continuum.

Table 2 gives the height of the oxygen bump in units of  $h\sigma$  where

$$h = (g(\Delta E)\eta At)^{1/2}$$

and  $g(\Delta E)$  takes into account the energy resolution of the detector.  $g(\Delta E) \leq 1$  and tends to 1 when  $\Delta E \rightarrow 0$ ; a rough estimate based on comparison between Fig. 1a and b gives  $g(150 \text{ eV}) \simeq 0.3$ . In the present experimental situation ( $A \geq 100 \text{ cm}^2$ ,  $t > 60 \text{ s}$ ,  $\eta \simeq 0.2$ ) values of  $h > 10 \text{ (cm}^2 \text{ s)}^{1/2}$  are common and  $h \simeq 1,000$  possible (on satellite experiments). The oxygen feature is therefore a sensitive indicator of the molecular hydrogen abundance in direction of the Crab Nebula.

At present, data on the soft X-ray flux from the direction of the Crab Nebula are available only at energies near and above 1 keV, where the absorption effects are completely within the present experimental uncertainty of the measured flux. We cannot therefore carry out comparisons. In the near future,

however, observations particularly aimed at observing the oxygen feature, (Griffiths, personal communication), will extend the available information towards lower energies and allow significant comparison between theory and experiment.

Some comments are necessary about the  $H_2$  absorption cross section. Between 0.1 and 1 keV there are estimates of  $\sigma_{H_2}$  which differ by a factor as high as 1.5 (ref. 10) from the one we used and give rise to an oxygen absorption edge higher by up to a factor  $\simeq 2$  at  $R = 0.5$ . In the absence of firm theoretical and experimental indications, we decided to use the most widely adopted cross section value in order to obtain results easily comparable with other calculations.

In spite of such an uncertainty, comparisons between calculated and measured spectra of the Crab Nebula X-ray flux are still worthwhile.

Application of this method to other X-ray sources, for which observations at sufficiently low energy already exist (see for instance ref. 11), can be made provided that first, the source distance or the hydrogen column density in the source direction is known and, second, reasonable assumptions on the source X-ray spectrum in absence of absorption are possible.

## Transient short time periodicities in the optical emission from Cyg X-1

TEMPORAL structure down to the millisecond time scale has been observed in the X-ray emission of Cyg X-1 (ref. 1). This has been interpreted as evidence of instabilities in the accretion disk surrounding a black hole<sup>2-4</sup>, lasting for approximately the orbital period of the infalling matter. We report here observations of modulated optical emission from this source with a period of  $\sim 83$  ms. The modulated emission was detected in two sets of observations as transient events lasting  $\sim 10$  min. This is the first evidence of strong emission at optical wavelengths from the X-ray source in the Cyg X-1-HDE226868 system.

The short period variations in optical emission were investigated with a photometric arrangement on the 91-cm telescope at the Catania Astrophysical Observatory. Single photon pulses and 1 kHz reference signal were recorded on magnetic tape, and the counting rate for 1-ms intervals subsequently transferred to digital tape. Computer analysis included correction for variable atmospheric absorption, Fourier analysis with the Cooley-Tukey (FFT) algorithm and count rate folding. The time base accuracy is 1 part in  $10^8$ , achieved by daily checking against the BIH international time scale using a 5-MHz radio link.

Systematic observations of both comparison stars and Cyg X-1 (when quiet) confirms that scintillation noise cannot

Fig. 1 Power density spectrum of the event of June 11.06111 and of the comparison star.

simulate a statistically significant modulation above a few Hz. The statistical distribution of the fluctuations in the Fourier spectrum is quite consistent with that expected from counting statistics, and we therefore deduce a sensitivity for our survey of 0.1% pulsed fraction with 99% statistical confidence in the frequency range 5–500 Hz.

Routine observations of Cyg X-1 were carried out in November 1973 and September 1974 with negative results. Observations were repeated in June 1975 after the observation of a new flare by the X-ray equipment on the *ANS* satellite<sup>5</sup>. Analysis of the data has revealed that a strong pulsed component appeared at 01.28 UT, June 11. The pulsation with a period of  $83.531 \pm 0.008$  ms lasted for  $\sim 10$  min. After this event no significant power was detected in the Fourier spectrum of Cyg X-1, nor in the check performed on the comparison star soon afterwards (Fig. 1).

The light curve of the pulsation, obtained by folding the counting rate module 83.531 ms, shows a very regular structure. The periodicity detected by Fourier analysis is caused by falls of intensity with a duty cycle near 25% (Fig. 2) naively suggesting an eclipsing phenomenon.

Figure 3 shows the time evolution of this event in steps of 30.72 s from the beginning of the tape to the merging of the pulsation in the background fluctuations. In this plot we have a clear picture of the settling of the pulsations. In fact, we observe that the modulated component is superimposed on the steady-state luminosity of the source. This brightening can be

also observed in a plot of the counting rate integrated for 1 s. On this plot the modulation growth has a rise time of  $\sim 3$  s. It should be noted that the modulation period was not strictly

Fig. 2 Light curve of the modulated emission, obtained by folding  $\sim 100$  s of data.

Table 1 Data from flare events on Cyg X-1

Time	Period $P$ (ms)	$\Delta P/P$	Filter	Duration (min)	$\Delta L/L$
June 11.06111 UT	$83.531 \pm 0.008$	$10^{-4}$	Grey ( $\times 10$ )	10	3.5 per cent
July 18.00410 UT	$83.714 \pm 0.008$	$2 \times 10^{-4}$	R	> 10	2.5 per cent
July 18.03674 UT*	$83.592 \pm 0.008$	$\geq 2 \times 10^{-4}$	B	> 6	3.7 per cent
July 18.04854 UT*	$83.592 \pm 0.008$	$\approx 2 \times 10^{-4}$	Grey ( $\times 10$ )	> 8.5	4.2 per cent

\*Probably related to the same event.

constant during the event, as shown by a significant variation in the phase of the minima. We estimate that during the event the period fluctuated by  $\sim 1$  part in  $10^4$ .

A similar activity in the source was observed one month later. On July 18 several events occurred in the space of  $\approx 1$  h. The data are given in Table 1. The light curves of the events in

because of the large luminosity of the spots which could come only from a non-thermal process.

Alternatively, if the phenomenon is associated with a rotating body, one cannot explain the variations of the period observed without assuming a triple star. In this case the period variability implies an orbital velocity  $> 300 \text{ km s}^{-1}$  for the rotating body.

Fig. 3 Evolution of the June event. Each plot corresponds to the folding of  $\sim 30$  s of data.

July are quite similar to those of June except that the duty cycle of the drop in intensity is here closer to 50%. Some ambiguity can arise in the time separation of the events. We assumed that the period given by Fourier analysis (the mean period) identifies each individual event. We stress that differences in period are quite noticeable, although small ( $\sim 1$  part in  $10^9$ ). The luminosity of the modulated emission can be estimated assuming that the bulk of the optical luminosity comes from the supergiant blue star HDE226868, and that this has the absolute visual magnitude of  $-6.5$ , corresponding to its spectral type. This gives a surprisingly high luminosity for modulated emission  $\sim 10^{35}$ – $10^{36} \text{ erg s}^{-1}$ .

Very qualitatively, such a periodicity in the optical emission could fit the popular accretion disk models for Cyg X-1. We may assume that this optical emission is generated by instabilities in 'spots' in the disk. Our data would then indicate that such instabilities arise in a rather limited region at a distance of a few hundred kilometres from the black hole. Difficulties arise

We thank Mr M. Mastropietro, Mr F. Pica, Professor G. Godoli, the staff of O.A.C., and Dr G. Spada for their help.

## Entropy production by black holes

HAWKING has shown<sup>1</sup> that black holes, treated quantum mechanically, emit black body radiation of temperature  $T = 10^{-7} (M_{\odot}/M) \text{ K}$ , and hence evaporate—if isolated—on a time scale<sup>2</sup> of  $\sim 10^{66} (M/M_{\odot})^3 \text{ yr}$ . Energy arguments<sup>1,3,4</sup> suggest that a black hole can be assigned the entropy

$$S_{\text{bh}} = 4\pi GM^2 k / \hbar c \sim 10^{77} k \sim 2 \times 10^{18} S_{\text{H}}(M/M_{\odot})$$

where  $S_{\text{H}} \sim 40(M/M_{\text{p}})k$  is the entropy of a hydrogen cloud from which the black hole is assumed to have formed,  $M_{\text{p}}$  is the mass of the proton, and  $k$  is Boltzmann's constant. This implies that when a hydrogen cloud of mass  $1M_{\odot}$  collapses into a black hole, the entropy of the (uncollapsed) galaxy [ $\sim 10^{12} S_{\text{H}}(M_{\odot})$  and more] would increase by a factor  $\sim 10^6$ . In other words: something hardly observable, namely the collapse of one star, would increase the entropy of our cosmic neighbourhood by a large factor. We endeavour to resolve this apparent puzzle.

To begin with, it must be remembered that in 'normal' conditions, matter has an entropy particle  $s \sim 1$ , ( $s = SN^{-1}k^{-1}$ ) where  $N$  = particle number;  $s$  varies between  $\lesssim 1$  (for example for electrons at temperatures  $T$  below the Fermi temperature  $T_{\text{F}}$ ) and  $\lesssim 90$  (for dispersed hydrogen of critical cosmological density  $a \sim 10^8 \text{ K}$ );  $s \sim 4$  for an extreme relativistic ideal gas. When a star forms by contraction of a cloud,  $s$  ( $\sim -\ln(n\lambda^3) + 5/2$ ) decreases from  $s_{\text{cloud}} \sim 40$  to  $s_{\text{star}} \sim 10$  (where  $n$  = particle number density,  $\lambda = h/(2\pi mkT)^{1/2}$  is the thermal de Broglie wavelength), but the second law of thermodynamics is not violated because the initial entropy has been converted into thermal radiation. If the star continues to shrink, its entropy

decreases still further, and again the excess entropy goes into thermal radiation. Following the matter through, we find a black hole of  $1M_{\odot}$  to have a rather small relative entropy at formation smaller than that of a neutron star. On the other hand, an isolated black hole evaporates within  $t_{\text{evap}} = 10^{66} (M/M_{\odot})^3 \text{ yr}$  and thereby emits black body radiation of temperature  $T$ . For complete evaporation, the vacuum must be large enough to take this black-hole energy. In filling this volume, the radiation randomises and acquires precisely the entropy given above; which is  $10^{18} (M/M_{\odot})^2$  times larger than that at formation.

This suggests the following resolution of our puzzle: a black hole forms on the collapse time scale  $t_{\text{coll}} = GM/c^3 = 10^{-5} (M/M_{\odot}) \text{ s}$ , with an entropy at birth smaller than that of its building blocks. Thereafter, if left alone it irreversibly evaporates on the (huge) time scale  $t_{\text{evap}}$ , with a (small) entropy production rate  $S \sim S_{\text{bh}}/t_{\text{evap}}$ . This implies that the entropy of the Galaxy is hardly affected by black hole formation. The so-called entropy of a black hole is the entropy it would produce during its irreversible evaporation.

Our suggested resolution can be made more explicit by noting that the entropy of an arbitrary thermodynamic system is defined as a hypersurface integral over the entropy four-current density  $s^a$ ,

$$k^{-1} S[\Sigma] = \int_{\Sigma} s^a dx_a^*$$

with  $s^a$  a future time-like vector inside the substratum (third law),  $s^a = 0$  in vacuum, and  $s^a \geq 0$  throughout (second law). In flat space-time,  $\Sigma$  is to be the hyperplane normal to the observer. In an asymptotically flat space-time,  $\Sigma$  will be chosen tangential to a distant observer's normal hyperplane; but in general there is a continuous arbitrariness in the choice of  $\Sigma$  in non-static domains. Such an arbitrariness implies that there will be a minimum and a maximum entropy for each space-time point  $x$ , namely the above functional  $S$  for the 'earliest' and the 'latest'  $\Sigma$  through  $x$ .  $S_{\text{min}}(x)$  and  $S_{\text{max}}(x)$  are equal for  $s^a = 0$  in the enclosed domain, that is, if all thermodynamic processes taking place are reversible, and almost equal for slow processes. An extreme situation occurs when a black hole forms, because then  $\Sigma$  should avoid some ill-understood space-time domain inside the hole: at certain (distant) observer times,  $\Sigma$  must cut through the black hole interior which cannot be observed in the classical (non-evaporation) limit. But the Cauchy development makes unique predictions (in principle) which can be used to calculate  $S[\Sigma]$ . And a glance at Fig. 1 shows how a distant observer notices the evaporation of an isolated black hole. In this two-dimensional conformal space-time diagram, light rays propagate at  $45^\circ$ ; angular degrees of freedom are suppressed; the collapsing star is represented by some of its (time-like) worldlines including the worldline of its centre (with a classically singular portion marked '?'). Flashes of radiation are emitted during the collapse and at the end of evaporation (when  $T(M)$  diverges, and a singularity forms). The entropies in the consecutive space sections  $\Sigma_1, \Sigma_2, \Sigma_3$  are of order  $S_{\text{H}}, \alpha S_{\text{bh}}, S_{\text{bh}}$  respectively, where  $\alpha$  is smaller than, but of the order of, unity.

These statements are at variance with those of Hawking<sup>5</sup> or earlier authors<sup>6</sup> who assign a time-independent value  $S_{\text{bh}}$  to the entropy contained inside the event horizon of a black hole, and which I consider untenable for the reasons given above. In particular,  $S_{\text{bh}}$  is  $10^{18} (M/M_{\odot})^2$  times larger than the entropy determined by local observers inside the black hole! And infalling observers cannot be discarded as 'unphysical': if our Galaxy contracted within its Schwarzschild volume, we would have another month to live under almost present-day conditions—not at almost infinite entropy density—for which period some of us may like to have predictions.

If we accept this, black holes of the same mass, spin, and charge can have different entropies, depending on their ways of

Fig. 1 Conformally finite radial space-time section through an isolated collapsing star (Penrose diagram).

formation. The highest entropy would be obtained for a black hole formed from the coldest possible radiation—radiation at its evaporation temperature. In this case, and only in this case, would evaporation be an isentropic process,  $S_{bh}$  being (already) the entropy at formation. Such black holes can exist in thermal equilibrium with their surroundings, but they cannot form<sup>5</sup> spontaneously from radiation unless their mass is below  $10^{-5}g$ , (corresponding to temperatures above  $10^{32}K$ ); they have to be synthesised from lower entropy ones.

What do we know about the entropy in the Universe? In our cosmic neighbourhood, the comoving entropy is nearly constant and given by that of the 3 K background radiation. Present-day matter contributes<sup>7</sup>, at most, a fraction  $3 \times 10^{-7}$ , (whose slow increase makes life possible). The comoving entropy would be maximal if all matter were converted into heat of uniform temperature; processing through black holes could in principle achieve this as local conservation laws (such as baryon number conservation) are thereby transcended. If this were achieved at time  $t$  ( $\geq t_0$ , the present time), cosmic entropy would be raised by a factor  $\lesssim 10^8(t/t_0)^{1/2}$ . In particular, present-day cosmic entropy is  $\geq 0.1\%$  maximal.

This consideration arose from a conversation with H. Buchdahl, and was promoted by discussions with A. King and J. P. Lasota.

## Possible implications of the Rubin-Ford effect

AN anomaly in the distribution of radial velocities was reported for Sc 1 galaxies by Rubin *et al.*<sup>1</sup> They found different mean velocities in two nearby hemispherical regions (I and II, see Fig. 1), although the mean apparent magnitude was found to be the same for both sets.

One interpretation they advanced was that the Hubble constant differs in the ratio  $H_{II}/H_I \approx 1.25$  for the two regions, contradicting the cosmologists' canon.

In the RFR<sup>1</sup> paper, an arbitrary division of the Universe into two was made, which has no evident physical significance. A non-cosmological redshift has been suspected for the centres of rich clusters of galaxies, like Coma<sup>2,3</sup>, and the effect noted by Rubin *et al.* may be correlated with this.

To test this hypothesis we divided galaxies into two categories: first, those whose light does not encounter any important cluster of galaxies on its way to the observer (galaxies in region A), and second those situated behind or inside a cluster (region B).

Zwicky's Catalogue of Galaxies and Clusters of Galaxies (CGCG)<sup>4</sup> supplies us with a suitable set of clusters of galaxies. We have limited our study to clusters classified 'near' ( $V \leq 15,000 \text{ km s}^{-1}$ ) whose population was  $\geq 500$  (for 'compact' and 'medium compact' clusters) or  $\geq 1,000$  (for 'open' clusters), so that their density of matter or of radiation is sufficiently high. We added the Virgo cluster which was not included in the CGCG because it is too near. Lastly, to include the possible influence of the gravitational and radiation fields of the clusters, we have included in region B an area around each cluster whose radius is double that of the cluster.

Distances of clusters are given by Noonan's list of published radial velocities<sup>5</sup>. For some clusters not included in that list, estimations were made with three different methods: first we estimated the luminosity classes of Sc and Sb galaxies in clusters<sup>6,7</sup>; this immediately gave us a distance modulus. Second we checked our results for Abell clusters using Abell's method<sup>8</sup>. Third, the Uppsala catalogue<sup>9</sup> supplied us with some other radial velocities.

Since the list of galaxies of Rubin *et al.*<sup>1</sup> is unfortunately not yet published, we used the following: 41 faint radio-sources identified with galaxies<sup>10</sup>. We used all the galaxies in the list within the intervals  $13 \leq m_{\text{corr}} \leq 15.5$ , and  $4,800 \leq V \leq 20,000 \text{ km s}^{-1}$ , and 77 compact galaxies with absorption spectra from Zwicky's Catalogue of Selected Compact Galaxies (CSCG)<sup>11</sup>. The Rubin-Ford effect has already been confirmed for this type<sup>12</sup>. We used the same radial velocity interval as for radio galaxies and revised the list with more simple criteria—we chose all compact galaxies within this velocity interval whose spectra show absorption lines but no emission lines other than [O II]  $\lambda 3,727 \text{ Å}$ , and which lie in the magnitude interval  $13 \leq m_{\text{corr}} \leq 18$ .

In spite of a few criticisms<sup>13,14</sup>, the homogeneity of Zwicky's magnitudes within these limits, seems confirmed by the recent work of Paturel<sup>15</sup>, if a correction is made for declination dependence by the term  $\Delta m_{\text{dec}} = 0.0025 \delta (d^\circ)$ , and if the sample is limited to galaxies of given morphology. These factors do not interfere with our statistical calculations.

**Table 1** Statistical results for the compact galaxies and the radio galaxies

Region		A	B

Compact galaxies	<i>n</i>	53	24
	$m_{\text{corr}}$	$15.88 \pm 0.136$	$15.45 \pm 0.194$
	$V_{\text{km s}^{-1}}$	$11,147 \pm 582$	$11,376 \pm 809$
	HM	$0.84 \pm 0.026$	$0.94 \pm 0.033$

*n* is the number of galaxies,  $\langle m_{\text{corr}} \rangle$  is the mean apparent corrected magnitude (see text),  $\langle V \rangle$  is the mean radial velocity relative to the sun and,  $\langle \text{HM} \rangle$  is the mean value of the Hubble modulus.

All apparent magnitudes are taken from CGCG or CSCG. Corrections are also made for galactic absorption by the formula:

$$m_{\text{corr}} = m - A_{\text{pg}} = m - 0.25 \text{ cosec} |b|$$

The two samples of galaxies, with the outlines of region B are plotted in Fig. 1.

To study eventual abnormal redshifts, the best suitable parameter is the Hubble modulus (HM), defined:

$$\text{HM} = \log V - 0.2 m_{\text{corr}} = \log H - 0.2 M - 5$$

where  $H$  is the Hubble constant in  $\text{km s}^{-1} \text{ Mpc}^{-1}$ , and  $M$ ,  $m_{\text{corr}}$ ,  $V$  represent respectively the absolute magnitude, the corrected apparent magnitude and the radial velocity in  $\text{km s}^{-1}$  of a galaxy. With this parameter we can test either a variation of  $H$  (if the mean absolute magnitude has a sufficiently small dispersion) or an eventual deviation of the mean absolute magnitude, provided the distance-symbolic radial velocity ratio is regular enough. The results are given in Table 1, with standard errors.

We would like to make the following comments: first, we obtain the differences  $\langle m_{\text{corr}} \rangle_B - \langle m_{\text{corr}} \rangle_A = -0.26 \pm 0.218$  and  $-0.43 \pm 0.237$  respectively for radio and compact galaxies. These results do not depend on the value chosen for the absorption coefficient, since similar differences are obtained with the non-corrected magnitudes:  $-0.31 \pm 0.212$  and

$-0.33 \pm 0.246$ . Second, the differences of Hubble modulus are contrarily positive and highly significant:

$$\langle \text{HM} \rangle_B - \langle \text{HM} \rangle_A = 0.16 \pm 0.036 \text{ (radio galaxies)}$$

$$\langle \text{HM} \rangle_B - \langle \text{HM} \rangle_A = 0.10 \pm 0.042 \text{ (compact galaxies)}$$

Student's variable is,  $t = 4.4$  and  $t = 2.4$  respectively, which are significant with a quasi-certitude of more than 99.9 per cent and 98 per cent. These results can be compared with the values obtained for the same samples in the case of the subdivision of Rubin *et al.*

$$\langle \text{HM} \rangle_{II} - \langle \text{HM} \rangle_I = 0.02 \pm 0.045 \text{ (radio galaxies)}$$

$$\langle \text{HM} \rangle_{II} - \langle \text{HM} \rangle_I = 0.08 \pm 0.043 \text{ (compact galaxies)}$$

These results suggest the following. First, Sandage and Tamman<sup>14</sup> have suggested that the effect noted by Rubin *et al.* could be explained by a deviation from the normal distribution of absolute luminosity (that is, HM values) 'if the velocity field itself is inhomogeneous (clumped) and if the magnitude limits of the sample are very narrow'. This explanation does not seem available in our case. Indeed  $m_{\text{corr}}$  intervals of our samples are rather large and their redshift distribution is not clumped.

Second, for our samples, the differences of  $\langle \text{HM} \rangle$  in our test are clearly accentuated and concentrated in comparison with those obtained with RFR division. As a consequence the RFR effect should be associated with the difference of distribution of clusters between the two regions of Rubin *et al.*

Third, since the distributions of our galaxies, in both region A and B, are rather uniform on the map of the sky (see Fig. 1), any explanation of the observed effect by a motion of the observer seems to be excluded. This excludes also the explanation by abnormal galactic absorption proposed, for example, by Hartwick<sup>16</sup>. Besides, absorption in the clusters cannot explain the effect, but on the contrary, would increase the difference.

Fourth, it has been suggested that clustering itself could give rise to systematic differences of  $\langle \text{HM} \rangle$ . Indeed absolute magnitude selection effects were reported by van den Bergh<sup>7</sup>. But the systematic difference he found between field galaxies and

cluster galaxies in the Virgo cluster (0.35 absolute magnitude), in the opposite direction to the ones we obtained, favour the underestimation of HM values in the clusters. Furthermore, to test the possible influence of clustering on our samples, we divided them into three regions: C (galaxies belonging to a cluster), A\* and B\* containing the galaxies which remain in the original A and B regions. We found (including standard deviations): compact galaxies:  $\langle \text{HM} \rangle_{B^*} = 0.96 \pm 0.046$  ( $n = 15$ );  $\langle \text{HM} \rangle_C = 0.86 \pm 0.040$  ( $n = 12$ );  $\langle \text{HM} \rangle_{A^*} = 0.85 \pm 0.027$  ( $n = 50$ ); and for radio galaxies:  $\langle \text{HM} \rangle_{B^*} = 1.19 \pm 0.024$  ( $n = 12$ );  $\langle \text{HM} \rangle_C = 1.11 \pm 0.033$  ( $n = 12$ );  $\langle \text{HM} \rangle_{A^*} = 1.01 \pm 0.034$  ( $n = 17$ ). It is seen that  $\langle \text{HM} \rangle_{B^*} > \langle \text{HM} \rangle_C \geq \langle \text{HM} \rangle_{A^*}$  which suggests that the observed effect is not due to clustering.

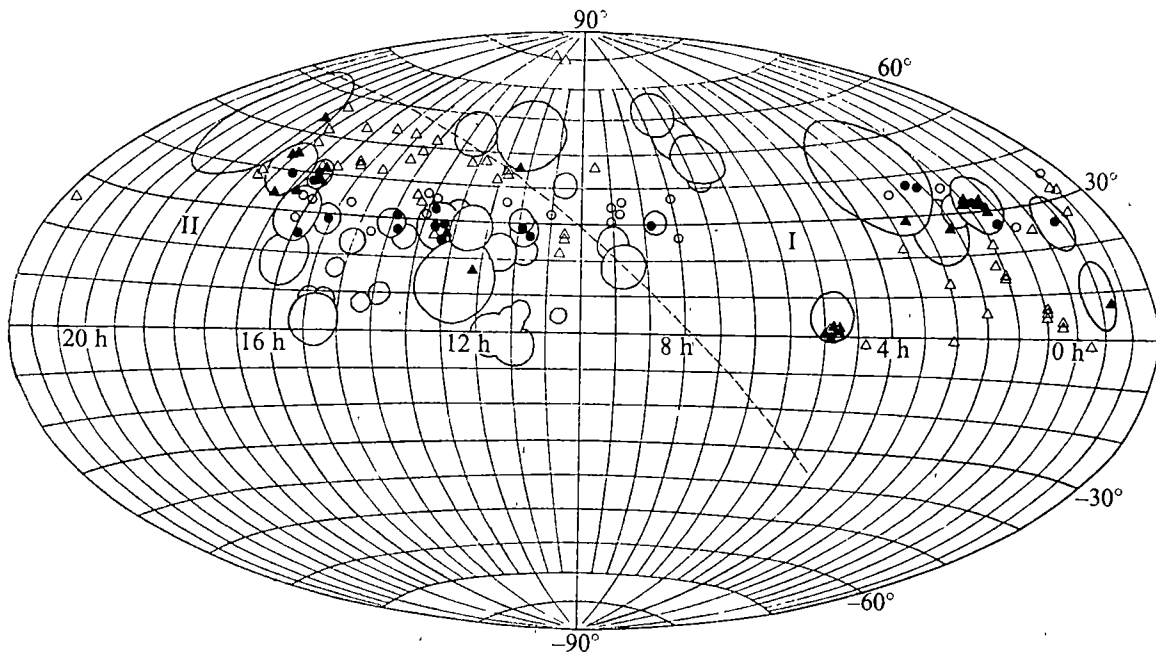

Finally, there remains, of course, the possibility that this phenomenon may be interpreted as Malmquist bias: for a magnitude limited sample, distant galaxies will be overluminous as compared to the mean. This could explain the observed differences of HM if the galaxies in region B are meaningfully more distant than in region A.

Such an interpretation is rather doubtful because we have checked that there is no significant difference of the mean geometrical distances between regions A and B ( $L_B - L_A = 200 \text{ km s}^{-1}$ , in symbolic radial velocity), so that the observed velocity difference cannot be interpreted in this way ( $\langle V \rangle_B - \langle V \rangle_A = 2,412 \text{ km s}^{-1}$  for radio galaxies) and because Fig. 2 shows that differences of the mean HM exist within each narrow redshift band, so that the total average difference cannot be explained by a simple difference between the distribution of galaxies with distance in the two regions.

We must finally mention the possibility that the mean absolute magnitude of the observed galaxies is not constant over the sky and take into consideration possible uncertainties in the analysis. Contingent, however, on the verification of the effect with an improved sample, we tentatively propose two alternative interpretations:

(1) Light emitted by distant galaxies is redshifted when passing through clusters of galaxies (an effect which could be connected with 'tired light' theories<sup>17,18</sup>) or (2) distant sources are more luminous when seen through intermediate clusters of galaxies, which could act, for example, as gravitational lenses.

**Fig. 1** Distribution on the map of the sky of the clusters of galaxies and of our two samples of galaxies, in equatorial coordinates. The clusters are represented by their outlines ○, radio galaxies in region A; ●, region B. △, compact galaxies in region A; ▲, region B. The dashed line is the border according to Rubin *et al.*

Fig. 2 ( $\log V$ , HM) diagram for (a) radio galaxies and (b) compact galaxies. The interval is divided into six narrow bands: I, 3.68–3.78; II, 3.78–3.88; III, 3.88–3.98; IV, 3.98–4.08; V, 4.08–4.18; VI, 4.18–4.30. In each band we calculate the mean of HM for region A (○) and region B (●). The difference between the two regions persists for each band.

We thank Professors Arp and De Vaucouleurs and Drs Paturel, Le Denmat, Jaakkola, Moles and Vigier for discussions and criticism, and Professor Heidmann and an anonymous referee for suggesting valuable improvements in the preparation of this paper.

## Response of electrons in ionosphere and plasmasphere to magnetic storms

MEASUREMENTS of total electron content (TEC) using the Faraday polarisation-rotation and dispersive-group-delay techniques were carried out at Fort Monmouth, New Jersey<sup>1,2</sup> (40.18°N, 74.06°W) using v.h.f. and u.h.f. beacon signals emitted by the satellite ATS-6. A comparison of TEC values obtained by both these techniques yields the total electron content of the plasmasphere. During the severe magnetic storms of September 15–16 and September 18–19, 1974, rapid increases with sudden onsets were observed in TEC as well as in plasmaspheric content,  $N_p$ . These increases were followed by long periods of low values of TEC and  $N_p$ .

Figure 1 shows one such variation of  $N_F$  (ionospheric content from Faraday rotation measurements),  $N_T$  (total content from dispersive-group-delay measurements),  $N_p$  ( $\equiv N_T - N_F$ , total plasmaspheric content) and  $\tau$  ( $\equiv N_F/N_{max}$ , slab thickness, where  $N_{max}$  is the maximum electron density at Fort Belvoir, Virginia (37.9°N, 75.5°W) before and after a sudden commencement (SC). The  $K_p$  indices for that period are also indicated in the figure. While there was an abnormal evening increase in  $N_F$ ,  $N_T$ , and  $N_p$  between 1930 and 0230 UT on September 14–15, a period of relatively low magnetic activity, the response of  $N_F$ ,  $N_T$ ,  $N_p$  and  $\tau$  to SC is quite noticeable. For two hours after SC,  $N_F$ ,  $N_T$ , and  $N_p$  increased rapidly; they oscillated for the next three hours, and then decreased rapidly to values well below the monthly average. After SC,  $\tau$  also increased; it declined after 1930. Unfortunately, Wallops Island ionosonde data were not available for the period after ~2400, September 15. At the time of their maximum values (1545 UT, September 15),  $N_F$  and  $N_T$  were ~100% larger than their corresponding monthly averages. At the time of its maximum value (1730 UT, September 15)  $N_p$  was ~70% higher than its monthly average. During the period of depressed content values,  $N_F$  and  $N_T$  were at one point (1830 UT, September 16), ~45% of their monthly values, while  $N_p$  was ~21%.

Fig. 2 shows the variations of  $N_F$ ,  $N_T$ ,  $N_p$  and  $\tau$  before and after SC, which occurred at 1434 UT (nearly the same time SC occurred in the previous storm) on September 18, 1974. Before SC,  $N_F$  and  $N_T$  were slightly lower or nearly equal to their monthly averages, while  $N_p$  was considerably below its monthly average.  $\tau$  behaved similarly this time to its behaviour during the period preceding SC in the previous storm. For four hours after SC,  $N_F$  and  $N_T$  increased very rapidly; they then declined rapidly, and reached values below their monthly averages six hours after SC.  $N_F$  and  $N_T$  recovered quickly and attained values near their monthly averages. After 0700 UT on September 19,  $N_p$  increased rapidly after SC and reached its maximum ~15 min before that of  $N_F$  and  $N_T$ ; it then declined rapidly to values below its monthly average and remained there throughout September 19.  $N_p$  was not, however, as depressed this time as it was after SC in the days following the previous storm. For two hours after SC,  $\tau$  increased rapidly; it then decreased to values not significantly different from its pre-SC values before both storms. At the time of their maximum values (1830 UT),  $N_F$  and  $N_T$  were ~120% larger than their corresponding monthly means and  $N_p$  (at 1800 UT) was 67% larger than its monthly mean.

The average behaviour of  $N_F$  and  $\tau$  during geomagnetic storms at mid-latitudes has been discussed previously<sup>3</sup>. It was determined that  $N_F$  is characterised by an initial positive (a total ionisation enhancement relative to monthly mean values) phase lasting a few hours, followed by a negative phase (a total ionisation reduction) of a much longer duration, possibly lasting a few days. During the positive phase,  $\tau$  is also enhanced because the relative increases in  $N_F$  are greater than those in  $N_{max}$ . As indicated by Figs 1 and 2, the storms of September 15–16 and September 18–19 are not atypical, as their behaviour was similar to the average behaviour.

Fig. 1 Variation of  $N_F$ ,  $N_T$ ,  $N_P$ ,  $\tau$  and  $K_p$  from 1745 UT, September 14, 1974 to 2230 UT, September 16, 1974. Monthly averages of  $N_F$ ,  $N_T$ , and  $N_P$  are indicated by  $\times$ .

Fig. 2 Same as Fig. 1, but from 2000 UT, September 17 to 2400 UT, September 19, 1974.

The radio beacon experiment (RBE) of the ATS-6 yields new information regarding the behaviour of the plasmaspheric electron content,  $N_p$ , during magnetic storms. The RBE contains two relevant experimental modes. The first uses the Faraday rotation technique for determination of total electron content. Since the rotation is magnetic-field dependent, its value is weighted heavily in the vicinity of the Earth and it is assumed that the Faraday technique yields integrated content values ( $N_F$ ) to heights of  $\lesssim 1,500$  km. The second uses the dispersive-group-delay technique in which the phase of the modulation envelope between a carrier and its sideband is compared at two frequencies. Since the phase is insensitive to the Earth's magnetic field, this technique yields the number of electrons,  $N_T$ , along the entire path from the geostationary ATS-6 to the observer. The difference between the two, that is  $N_T - N_F$ , yields the total electron content above  $\sim 1,500$  km, which is referred to as the plasmaspheric content,  $N_p$ .

The increase in  $N_p$  following SC tends to support the theory that increases in the total electron content during the positive phase are caused, at least in part, by the lifting of the F layer to regions of reduced recombination. Apparently, the upward fluxes of electrons after SC cause  $N_T$  to increase faster than  $N_F$ . This means that some of the electrons which were counted by the Faraday rotation technique had moved from the ionosphere to the plasmasphere.  $N_T$  increased, since the diffusing electrons had reached regions of reduced recombination.  $N_F$  increased at a slower rate, since, while recombination was reduced, some electrons had moved to the plasmasphere and were no longer counted. The net result was enhancement of plasmaspheric content.

The negative phase of the magnetic storm, which commenced about five to six hours after SC, occurred simultaneously with  $N_F$ ,  $N_T$ , and  $N_p$  for both storms. As was previously suggested<sup>4</sup>, the heating effects of the neutral atmosphere, which disturb the normal production and loss processes in the ionosphere, were responsible for depletions of the ionospheric electron content. The plasmaspheric content, which is unaffected by normal production-loss processes, since these are ineffective at such heights, was very depressed compared to its corresponding mean monthly value. The plasmasphere is maintained by diffusive fluxes from the ionosphere. With the reduced values of the ionospheric densities, the plasmasphere was depleted by downward fluxes which seek to maintain hydrostatic equilibrium in the topside ionosphere.

## Simultaneous small and large scale irregularities in the ionospheric F region

THE study of scintillation-producing irregularities over Australasia indicates a continuous spectrum of scale sizes of ionisation clouds<sup>1</sup>. Amplitude scintillations are most sensitive to small scale irregularities, peaking at 1 km transverse to the magnetic field<sup>1,2</sup>. The presence of large scale irregularities could be detected from the measurements of total electron content (TEC), using the Faraday rotation or dispersive-Doppler technique, on v.h.f./u.h.f. transmissions from satellites orbiting the Earth. There is considerable evidence of large wave structures in the F region; the wavelength and period of large ionospheric disturbances are similar to those of large scale gravity waves<sup>3,4</sup>.

Fig. 1 An example of simultaneous occurrences of large fluctuations in TEC and scintillation activity.

Amplitude scintillation studies and TEC measurements have previously been conducted separately. This omission makes it difficult to cover the complete spectrum of irregularities since each of the techniques, used separately, has a limited spectral bandwidth. We therefore simultaneously recorded large and small scale ionisation structures in the F region. Amplitude scintillation studies were conducted using radio transmission from five US Navy navigational satellites (NNSS), at a frequency of 150 MHz. The recording station was in Brisbane (27°S, 152.9°E). Phase-locked receivers were used to receive radio signals from NNSS at two coherently related transmissions at frequencies 150 and 400 MHz. By employing a dual phase-locked receiver to monitor the phases of these two signals (and a suitable mixing technique to remove the vacuum Doppler) dispersive-Doppler phase shifts were measured. In turn, TEC computations were performed using the phase recordings. Thus, it was possible to record amplitude scintillations and TEC variations for the same satellite passes.

Figure 1 shows an example of simultaneous amplitude scintillations and TEC recordings obtained on November 24, 1973. Solid curves are TEC variations against sub-ionospheric latitude, assuming the irregularity height of 400 km above the Earth's surface. The corresponding scintillation regions are indicated by horizontal bars TEC and corresponding scintillations were recorded for NNSS passes with the following local times of the nearest approach: 1-1 (1756 LT), 2-2 (2046 LT) and 3-3 (2135 LT). The scintillation index (SI) varied from 60% (SI=3) to 100% (SI=5) modulation of the received signal (full definition of SI has been given elsewhere<sup>5</sup>). It can be seen that strong TEC variations were associated with pronounced scintillations during the second pass. The regions, where these two disturbances occurred were, however, largely different. A more typical situation is shown for the third pass when the large and small scale fluctuations occurred in a similar area.

We obtained 42 simultaneous TEC and amplitude records for November 1973 to January 1974. Forty per cent of the cases were recorded during quiet (SI=0) ionospheric conditions all with TEC amplitude (that is, percentage

deviation of TEC from the background ionisation) in the 0–5 range. During disturbed conditions ( $SI=1-5$ ), 5% of the recordings had TEC amplitude 0–5, 38% had amplitude 5–10 (average 7.2) and 17% had amplitude 10–15 (average 13.6).

Relatively large TEC fluctuations were always associated with scintillation activity, and there were very few scintillations whenever TEC amplitude was less than 5% of the background ionisation. The latitudinal occurrences of TEC fluctuations and simultaneous scintillations were also examined. There were 10 cases for which there was complete spatial coincidence, 9 cases of partial coincidence and 5 of no coincidence at all.

In general, TEC fluctuations had a larger horizontal extent than scintillations. They exhibited a quasi-periodic structure with the wavelength lying in the range 300–600 km.

It seems, from the above considerations, that there is good temporal correlation between the occurrence of large and small irregularities in the ionosphere. The spatial coincidence, however, of both structures is not complete. This may indicate that gravity waves, which are responsible for the quasi-periodic structure of TEC fluctuations, do not necessarily produce small scale irregularities. The simultaneous temporal occurrence of both structures seems to be due to a common source. It has been suggested that the source of ionisation clouds, responsible for mid-latitude scintillations, is located in the evening sector of the auroral zone<sup>3</sup>. There is also strong evidence that large scale gravity waves, observed at mid-latitudes, are produced in the evening sector of the auroral zone<sup>4</sup>. Thus, it is likely that there is a bulk motion of ionisation patches causing scintillations are wave motion associated with TEC fluctuations. Both structures once originated in the auroral zone seem to propagate towards the equator.

## <sup>40</sup>Ar/<sup>39</sup>Ar dates for spreading rates in eastern Iceland

RADIOMETRIC dates for eastern Iceland have shown considerable scatter (see ref. 1 for a summary). This paper describes the results of the systematic dating of a stratigraphically continuous sequence of lavas (see Figure 1 for the sample locations; nomenclature follows ref. 2, from which further details can be obtained). As some of the lavas have experienced low-grade hydrothermal alteration<sup>3</sup> the <sup>40</sup>Ar/<sup>39</sup>Ar step-heating method was chosen, and the results of determinations on 18 samples from 11 sections are set out in Table 1.

Plateau ages are based on those steps whose apparent ages do not differ from the plateau mean by more than their estimated analytical error (s.d.). Means were calculated in two ways: weighting by the fraction of <sup>39</sup>Ar released during the step, and the inverse of the variance. As the difference in most cases was very small (suggesting the two methods are not independent) ages calculated using the latter method have been used in subsequent parts of this paper as it is the one in common use. All plateaux had at least four steps and comprised > 50% of

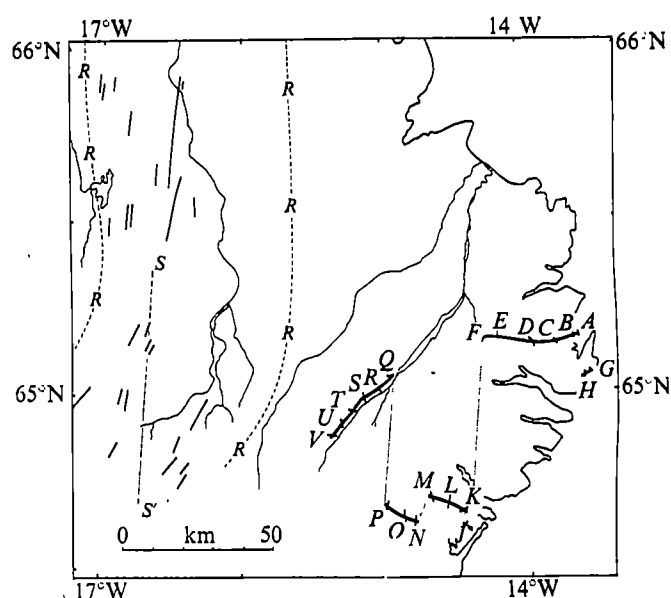

Fig. 1 Map of eastern Iceland. The large letters show the locations of the sections sampled by Dagley *et al.*<sup>2</sup>, from whose collection the dating samples were selected. The dashed lines  $R$  denote the limits of the present active zone, and the heavy lines within this zone signify post-glacial fissure eruptions. The line  $S-S'$  approximates the centre of the active zone for the sections  $A-V$ . Map after ref. 2 and 15.

the <sup>39</sup>Ar released. Random deviations from the plateau occurred at both the lowest and highest temperature steps. In the case of K9 the initial step, involving 21% of <sup>39</sup>Ar, gave an apparent age of  $143 \pm 16$  Myr, and though steps 2–5 gave a convincing plateau, this plateau age is significantly higher than that of K36 and appears anomalous in the succession; it therefore seems likely that some excess argon has been retained at all temperatures. As a saddle-shaped curve is a common feature of samples containing excess argon, of which the lowest part is sometimes horizontal enough to be considered a plateau<sup>4,5</sup>, there is therefore the possibility that other samples which gave a high age for the initial step have a systematically high plateau age, but as the initial step of no other sample was so high or comprised so much <sup>39</sup>Ar, the error is considered negligible.

Fig. 2 Possible flow profiles. Three curves of the form of equation (2) for different values of  $k$  are given. Also shown are three observed horizons indicated by symbols: circles, Bodvarsson and Walker<sup>6</sup> Fig. 3, section  $BB'$ , profile between horizons H.T. and Gr.P; + and × respectively from right and left horizons of Fig. 2, Walker<sup>3</sup>. Curve  $A$  is assumed steepest flow profile (stratigraphic horizon) used to give probable minimum correction. Inset: Idealised section through lava pile. The source is to the left; the vertical scale is exaggerated.

§ Estimated, as lowest temperature step not measured.

With this exception, the stratigraphic consistency of the dates shows the validity of the method.

Table 1 (and Fig. 3) shows that there can be no major time-gaps in the succession, and therefore affords no support for the large westward displacement of the spreading zone, postulated by Ward, which would result in a hiatus between sections P and Q<sup>6</sup>. Nor has a hiatus been found in the Western Iceland succession<sup>8</sup>. Table 1 also shows that evidence for glaciation is found in sections as old as P<sup>2</sup>, ~ 5.5 Myr ago.

Calculations of spreading rates are not possible until allowance has been made for the fact that as a flow (or the group of flows which constitutes a section) has considerable lateral extent, it may be sampled over a range of distances from the spreading zone. In eastern Iceland the lava groups, on average, increase both their dip and thickness in a regular manner as they are followed westward<sup>9</sup>, so that, in principle, the distance of a flow from the axis of the spreading zone can be defined uniquely, though somewhat arbitrarily, by measuring it at some specified reference height within the lava pile (Fig. 2, inset). If a sample was collected at a different height, its distance from the spreading axis can be corrected to that height, provided the cross-sectional shape of a lava flow ('horizon') is known. In practice there are complications; the lava pile has been distorted, there are internal irregularities and erosion has removed its top. Thus, to make the correction it is necessary to know the position of the sample in the original pile, as well as the shape of the average horizon, both of which have to be deduced indirectly.

The height of the original top of the pile can be inferred from a study of the dyke swarms and the zeolite grade metamorphism, and the two methods give consistent results<sup>3,9</sup>. A map showing the height of the original surface (taken as 600 m above the top of the analcite zone) has been published<sup>10</sup>; it varies from 0.7 to 1.7 km above present sea level.

The deduction of the shape of unmapped parts of the pile is not so easy, but depends upon the regularity of profile seen in exposed sections<sup>9</sup>. If it is assumed that a group of lavas thins away from the spreading zone according to

$$z = z_0 \exp(-kx) \quad (1)$$

where  $z$  and  $z_0$  are the thicknesses of the group at two places separated by a distance  $x$  (measured horizontally perpendicular to the spreading zone), and if it is further assumed that the flows of the pile have the same profile over a significant distance

(Fig. 2, inset), then it necessarily follows that the horizons have the form

$$h = h_0 \exp(-kx) \quad (2)$$

where  $h_0$  is an arbitrary depth that sets the zero of  $x$  (Fig. 2).

$k$  can be estimated from reports in the literature in a number of ways; the rate at which the dip decreases in a vertical traverse of the pile  $[(d/dh)(dh/dx)]$  is simply  $-k$ . Dagley *et al.*<sup>2</sup> state that "there is a regular upward decrease in the dip of a lava flow averaging 1° per 170 m increase in altitude", which, since it does not depend upon the altitude, supports equation (1), and yields  $k = 0.102$ . A second method depends on the dip observed at a specified height in the pile: that at sea level near section A (estimated at about 1.3 km below the original surface) is given as 6–8° (ref. 2). If a mean of 7° is chosen, equation (2)

Fig. 3 Age of samples against distance from spreading ridge. Distances have been measured perpendicularly to the line S-S' of Fig. 1; in the upper part these distances have been used unaltered, but in the lower part they have been corrected to a reference height 1.5 km below the surface of the pile, according to curve A of Fig. 2. Errors in distance are unknown but could be large. Samples are identified by section letter, plus number where necessary.

gives  $k = 0.103$ . Figure 2 shows a number of curves obeying equation (2) with  $h_0 = 1.5$  km and different values of  $k$ . Also shown are some horizons described elsewhere (approximately perpendicular to the spreading axis), after correction to the inferred depth below the original surface. The actual profiles only approximate the curves from equation (2), and even then have a range of values of  $k$  from roughly 0.09 to 0.13. In addition, it should be noted that the mathematical model must breakdown as the profile approaches the surface, for the theoretical curves give some lavas extending to infinity, as implied in equation (1). Curve A of Fig. 2, an assumed extrapolation of the steepest of the three observed horizons, has therefore been used to make corrections, which are probably minimal.

Figure 2 is used to correct the sample positions to a common depth, taken as 1.5 km (the more obvious choice of the surface as reference height is precluded by the inadequacy of the model). The effect of the correction is most marked for the youngest and nearest-surface sections ( $R-V$ ), and results in an increase in the apparent spreading rate over the time spanned by these sections. The errors on the largest corrections are more than proportionately large, as they depend on the estimation of the sample position relative to the original surface, the orientation of the line  $S-S'$  and on the shape of the flow horizon near the surface, where the model breaks down and where field observation is lacking. The correction for sample V18 is, however, unlikely to be  $< 18$  km and is probably more, so that the spreading rate for the period from 10–2 Myr was probably uniform and not less than  $0.8 \text{ cm yr}^{-1}$  (half rate). At the present level of accuracy this is not distinguishable from the spreading rates on the Kolbeinsey Ridge to the north of Iceland ( $0.82 \text{ cm yr}^{-1}$  on the eastern side<sup>11</sup>) or the Reykjanes Ridge to the south [ $\sim 1 \text{ cm yr}^{-1}$  (ref. 12)].

The corrected part of Fig. 3 extrapolates, for zero age, to a position about 30 km east of the centre of the present active zone, but within the active zone. This figure would be reduced if larger corrections were applied; on the other hand, if the distance from the spreading axis were referred to a reference height nearer the surface the figure would be increased. Before this intercept can be interpreted, a detailed understanding of the zone in which the lava pile is formed is needed; suggested models involve an active width of 50 km (ref. 13) or 70 km (ref. 14), and therefore, considering the large possible errors in Fig. 3, no significance is attached at present to the non-zero intercept.

We thank Professor R. L. Wilson for suggesting this project, Dr J. W. Purdy for initiating it and the SRC for a grant for irradiation costs.

## Direct conversion of graphite to diamond under static pressure

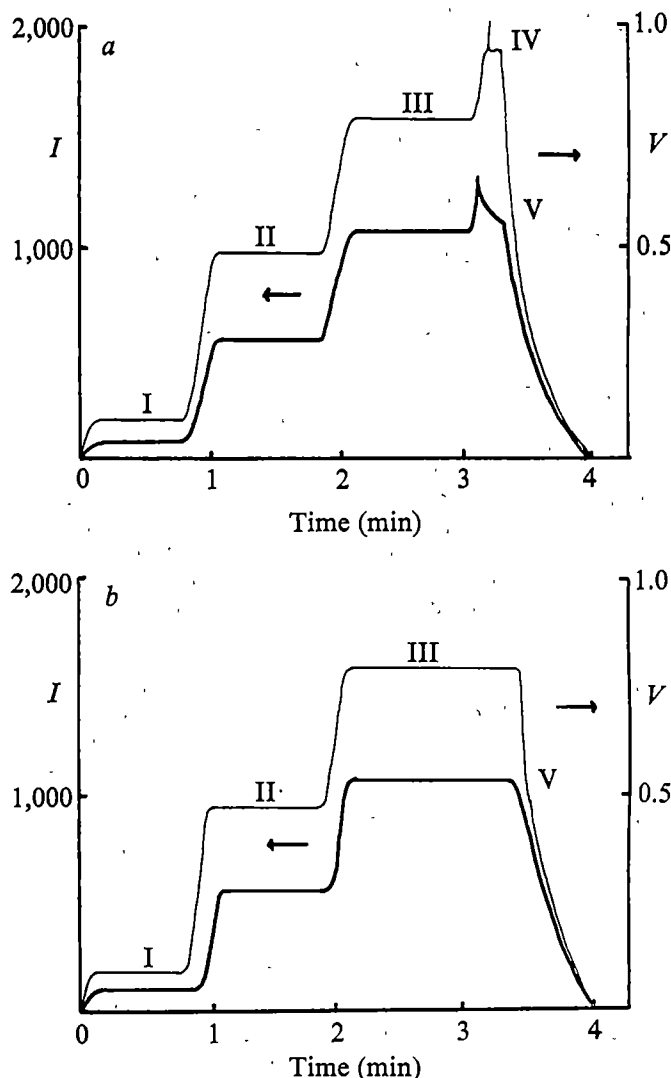

WE report the preparation of cubic type diamonds, by heating a graphite bar by passing an electric current directly through the specimen; we used a modification of the techniques developed in refs 1–4.

We obtained more than 60% of the theoretical yield. The transparent diamonds obtained were in the aggregated state, with a size of about 0.1 mm. The aggregate was found to be composed of a number of crystals with size of  $\sim 10$ – $20 \mu\text{m}$ , which is larger than the size (200–500 Å) of diamond crystals synthesised by flash heating<sup>5</sup>.

A spectroscopic grade graphite bar, 3 mm in diameter and 7 mm in length (about 80 mg), was used. The specimen was subjected to a pressure of  $140 \pm 10$  kbar, and then an electric current was passed through it. Figure 1 shows a plot of current–voltage against time: *a* is a typical case where diamonds were successfully obtained, *b* is a case where diamonds were not obtained.

The voltage was increased at fixed intervals and until step III, Ohm's Law was obeyed. When the voltage was increased to 0.95 V at step IV, a sudden increase in voltage and a decrease in the electric current were observed. The

Fig. 1 *a* and *b*, Current and voltage against time for spectroscopic graphite bar at 140 kbar. *a*, Voltage taken up to 0.95 V; *b*, voltage taken to 0.8 V.

Fig. 2 X-ray powder diffraction patterns of the original graphite and the heat-treated specimens. *a*, Original graphite; *b*,  $I, V = 0$  and  $P = 140$  kbar; *c*, specimen obtained from the experiment recorded in Fig. 1*b*; *d*, specimen obtained from the experiment recorded in Fig. 1*a*.

voltage was then maintained at a constant 0.95 V, and the electric current decreased gradually for about 20 s. This phenomenon was similar to the observations of Bundy<sup>1</sup>, but the conversion time of graphite to diamond in his experiment was said to be of 'millisecond' order, whereas the corresponding time in our experiments seemed to be of the order of seconds. Using the flash heating technique, homogeneous heating of the specimen should be obtained, with consequent rapid crystal transformation whereas using our resistance heating technique, a radial temperature gradient should be created. The core of the specimen would then be the first part to turn into diamond, and the transformation would subsequently propagate to the surface.

At step V, the heating power was purposely decreased. This was necessary to prevent the melting of the pressure medium, and contamination of the diamond.

If the voltage was increased to only 0.8 V, as shown in Fig. 1*b*, the transformation of graphite to diamond did not occur. The temperature at step IV in Fig. 1*a* may, therefore, be estimated, from the reaction diagram of Bundy<sup>3</sup>, to be 3,000–3,500 K.

The X-ray powder diffraction patterns of the original graphite specimen and the heat-treated specimens are shown in Fig. 2. By pressurising the original graphite, the hexagonal lattice of the graphite was distorted and partly converted to the rhombohedral lattice. Rhombohedral graphite was also obtained by grinding<sup>6</sup>. The rhombohedral lattice is stable on heating up to stage III and it was therefore concluded that the transformation to diamond in the metastable region of graphite must proceed through

a drastic change in the chemical bond. DeCarili and Jamison have also proposed that diamond is formed from the rhombohedral lattice of graphite<sup>7</sup>. Establishment of the mechanism of the transformation process will need, however, more detailed physicochemical experiments.

## Language perception of 2-month-old infants shows effects of both innate mechanisms and experience

VOICING differences distinguish two or more stop consonants in nearly all the world's languages. It has been found<sup>1</sup> that voicing distinctions for stops in word-initial position can usually be characterised by differences in voicing onset time (VOT), where VOT is defined as the time between the stop release burst and the onset of vocal cord vibration (voicing). For example, the English phonemes /p/ and /b/ differ in this way; voicing follows release in /p/, while voicing is approximately simultaneous with release in /b/.

Eimas *et al.*<sup>2</sup> found that American infants as young as 1 month old discriminated between the synthetically produced speech sounds, [b] and [p]. These infants failed, however, to discriminate between speech sounds which were separated by the same VOT difference as [b] and [p], but were members of the same phonemic category in English. (This result has been replicated for stimulus separations as small as 20 ms VOT and as large as 100 ms VOT<sup>3</sup>.) Thus, the infants, who do not yet produce these sounds, showed the same discrimination pattern as American adults; discrimination between phoneme categories was better than discrimination within phoneme categories<sup>4</sup>. Consequently, it has been proposed that the perception of voicing may be accomplished by innate perceptual mechanisms specifically tuned to perceive speech. To determine whether the discrimination of the English voicing distinction is independent of earlier linguistic exposure, I have investigated the discrimination of voicing onset by infants reared in a linguistic environment in which the English voiced/voiceless distinction is not used.

Kikuyu, a Bantu language spoken in Kenya, has only one labial stop, a prevoiced /b/, in which voicing substantially precedes articulatory release by an average value of 64 ms. The language distinguishes between prevoiced and voiced stops for other places of articulation, but Kikuyu has no stops in which voicing onset is substantially delayed relative to stop release as in the English voiceless, /p/, /t/, and /k/.

Discrimination was tested by a conditioned non-nutritive sucking habituation technique<sup>5</sup>. The infant sucked a blind nipple, which was attached to a pressure transducer. Criterial sucks whose amplitude exceeded an individually adjusted threshold (the baseline rate was approximately between 15 and 30 sucks min<sup>-1</sup>) activated a counter and resulted in 1 s. of sound presentation. The sound source was a tape loop with alternating syllables such as [ba] and silent intervals each 500

ms in duration. The sound source was gated in and out by a variable resistance device to minimise clicks. One or more criterial sucks  $s^{-1}$  continuously maintained the auditory signal at a comfortable listening level that produced few startle responses.

Typically, the infant's sucking rate increased over the baseline rate after a few min of pairing sucking and sound, presumably because of the reinforcing properties of the sound; eventually, however, the sucking rate decreased. This decrease has been attributed to habituation to the sound or its reinforcing value<sup>2</sup>. When the sucking rate had decreased by  $\geq 20\%$  of the rate in the immediately preceding minute for two consecutive minutes or had decreased by  $\geq 20\%$ ,  $\geq 0\%$ , and  $\geq 20\%$  respectively in three successive minutes, the sound was changed without interruption. The experiment was terminated 4 min after the sound shift. The rationale for this procedure is that if the sucking rate increases after the sound shift relative to a control condition with no sound shift, the sound shift must have been discriminated.

All stimuli were generated on the Haskins Laboratories' parallel resonance synthesiser and had the same formant frequencies and amplitudes as the stimuli used by Eimas *et al.* In all there were six syllables, a labial stop followed by the vowel [a] with VOTs of: -30 (prevoiced), 0 (voiced), 10 (voiced), 40 (voiceless), 50 (voiceless), and 80 (voiceless), which would be identified by English speakers as /ba/, /ba/, /ba/, /pa/, /pa/, and /pa/ respectively.

There were three experimental conditions with the following VOTs: (-30, 0), (10, 40), (50, 80) and a control condition in which pre- and post-shift sounds were the same, distributed equally over the six VOT values. The order of the three experimental conditions was counterbalanced across subjects as was the order of sound presentation within each condition. The control condition was either first or last. Each infant participated in all conditions.

Thirty-six periurban Kikuyu infants with a mean age of 63 d (s.d. = 12 d) participated in the study. All infants had heard only Kikuyu spoken in the home.

As in previous investigations<sup>6</sup> using this technique with American infants, data were excluded for subjects who did not demonstrate adequate conditioning or habituation. Data were excluded if: (1) the pre-sound shift conditioning and habituation period was less than 4 min long and/or (2) if there were fewer than 15 sucks in either of the 2 min directly preceding the sound shift. The reason for the second criterion was that the infant had habituated too much, and consequently the stimulus would not be presented often enough to observe changes in its effect.

Analysis (unweighted means solution, repeated measures on two factors) of sucking rate in the 4 min directly preceding the sound shift indicated that all conditions were similar before the sound shift. (An analysis of variance revealed no significant effects of conditions or a conditions-minutes interaction.)

Discrimination was measured as an increase in sucking rate during the 2 min directly after the sound shift compared with the 2 min immediately preceding the shift. Analyses were performed using these difference scores. The analyses were *t*-tests, using split-significance levels ( $\alpha = 0.05/k$ , where  $k = 3$ ). The analysis of these reduced data required the assumption of zero main effects and interactions for subjects. Since an analysis of the full data set showed that the between subject differences were near zero, this seemed to be a reasonable assumption. Both the (10, 40) and (-30, 0) conditions were different from the control condition ( $P < 0.05$ ). The (50, 80) condition was not, however, different from the control condition; nor were there any significant differences among the three experimental conditions. Figure 1 shows the mean change in response rate for all four conditions.

Kikuyu infants thus made two linguistically relevant discriminations; they discriminated a [p] in which voicing preceded release from one produced with simultaneity of voicing and release, and they also discriminated a [b] produced with approx-

Fig. 1 Mean change in response rate per min as a function of experimental condition. The s. e. m. for the four conditions are: (-30,0) 3.24, (10,40) 2.77, (50,80) 3.58, and (control) 4.32.

imately simultaneous onset of voicing and release from a labial stop produced with substantial voicing lag [p]. It should be noted that adult Kikuyus showed the same discrimination pattern as the infants<sup>7</sup>. Thus, the ability to discriminate the voiced/voiceless distinction is not lost in the absence of relevant linguistic exposure, suggesting that this voicing distinction due to its psycho-acoustic properties is naturally discriminable.

The results of the present study differ from those of Eimas *et al.*, who found no reliable discrimination of the prevoiced/voiced distinction in American infants. Eimas<sup>3</sup> reports that American infants discriminated the prevoiced/voiced distinction. The stimulus separation used (70 ms) was, however, much larger than the one used here, and was of the order of three times larger than required for adult phoneme discrimination in any language that has been studied.

The differences between the present study and that of Eimas *et al.* seem to be attributable to differences in American and Kikuyu linguistic environments. Kikuyu infants hear only one labial stop, a prevoiced /b/. But they do hear prevoiced stops contrasted with their voiced counterparts for other places of articulation. Thus, they are exposed to the acoustic cue or cues underlying the prevoiced/voiced distinction. On the other hand, American infants do not hear prevoiced stops in their linguistic environment. Thus, the results suggest that previous exposure to the prevoiced/voiced distinction in the language or perhaps exposure to the acoustic cues underlying this distinction is a prerequisite for discrimination of the contrast. On the other hand, the voiced/voiceless distinction can be made in the absence of relevant linguistic exposure, since Kikuyu infants do not hear this voicing distinction used in their language. Thus, the results suggest that there is an interaction between nature and nurture; some phonetic or acoustic discriminations may be universal, whereas others seem to require previous relevant exposure.

This research was conducted under the auspices of the Child Development Research Unit, University of Nairobi, Nairobi,

Kenya, supported by a Carnegie Foundation grant and a grant from the US National Institute of Mental Health. I thank T. K. Landauer, John and Beatrice Whiting, and the Haskins Laboratory.

## Behavioural fever in teleost fishes

THE ectothermic lizard *Dipsosaurus dorsalis* has been shown to exhibit a behavioural fever<sup>1</sup> when injected with killed *Aeromonas hydrophila*, a Gram-negative bacterium pathogenic to mammals, reptiles, amphibians and fishes, causing haemorrhagic septicaemia<sup>2,3</sup>. The behavioural fever in lizards has been shown to have survival value<sup>4</sup>.

Mammals and birds use behavioural as well as physiological means to increase body temperature during a fever<sup>5,6</sup>, whereas ectotherms such as lizards and fishes are limited largely to behavioural means alone<sup>1,7</sup>. Evidence is accumulating that the hypothalamus controls thermoregulatory responses (both behavioural and physiological) in all classes of vertebrates, including fishes<sup>1,7-11</sup>. Drugs such as pentobarbitol which alter thermoregulation in mammals by acting on the hypothalamus<sup>12</sup> also affect behavioural thermoregulation in fishes<sup>13,14</sup>.

Fever results from the effect of pyrogens on the hypothalamus<sup>15,16</sup> by increasing the set points of the thermostat control centre<sup>1</sup>. Vaughn *et al.*<sup>1</sup> speculated that the behavioural component of fever might have evolved in early reptiles or even amphibians, and presented evidence for this in reptiles. We report here evidence that a similar behavioural febrile response exists also in fishes.

We tested eight bluegill sunfish, *Lepomis macrochirus* Rafinesque (120-155 mm standard length), and two large-mouth blackbass, *Micropterus salmoides* (Lacépède) (110-160 mm s.l.), matching the sample size of ten animals tested by Vaughn *et al.*<sup>1</sup>, plus an equal number of controls. The normal thermoregulatory behaviour of these species has been extensively studied<sup>17-21</sup>.

We allowed each fish to thermoregulate in a device which enables a fish to control water temperatures, and thus body temperatures, by its movements between two chambers of different temperatures controlled by photo-transistor relays which monitor the position of the fish. The operation of this device has been described previously<sup>17,18</sup>, having been based on an earlier design<sup>20-22</sup> which is similar in principle to that used by Vaughn *et al.*<sup>1</sup> for lizards. Recent work in our laboratory has shown that mean deep body temperatures in our device do not differ significantly from mean occupied temperatures, nor from mean water temperatures.

The fish were maintained in aquaria at 22-24°C, on a light-dark (LD) 12:12 photoperiod. Fish were tested individually. Each fish was allowed an introductory period of 24 h in which to reach its preferred final temperature (~30°C) and become acclimatised to it<sup>17</sup>. Then, mean occupied temperatures were monitored for a control period of 24 h. The fish was then injected intraperitoneally with 0.75 cm<sup>3</sup> of fish physiological saline containing 4 × 10<sup>8</sup> killed *A. hydrophila* cells, prepared as described by Vaughn *et al.*<sup>1</sup>, and thermoregulatory performance was monitored

Table 1 Mean preferred temperatures (±1 s.e.) before and after injection of *A. hydrophila* in ten fish

Species	s.l. (mm)	°C before injection	°C after injection	+ΔT (°C)
<i>Micropterus salmoides</i>	110	29.6±0.3	31.9±0.2	2.3
<i>Micropterus salmoides</i>	160	30.6±0.3	32.3±0.3	1.8
Grand mean (bass)		30.1±0.5	32.2±0.3	2.1
<i>Lepomis macrochirus</i>	120	31.9±0.2	33.4±0.2	1.5
<i>Lepomis macrochirus</i>	125	30.9±0.2	32.4±0.3	1.5
<i>Lepomis macrochirus</i>	130	31.6±0.3	34.4±0.3	2.8
<i>Lepomis macrochirus</i>	130	32.5±0.2	37.2±0.2	4.7
<i>Lepomis macrochirus</i>	145	27.9±0.3	30.4±0.2	2.5
<i>Lepomis macrochirus</i>	150	29.3±0.3	32.2±0.2	2.9
<i>Lepomis macrochirus</i>	150	30.8±0.2	33.8±0.3	3.0
<i>Lepomis macrochirus</i>	155	29.2±0.2	31.4±0.2	2.2
Grand mean (bluegill)		30.5±0.6	33.2±0.7	2.7
Grand mean (all fish)		30.4±0.5	33.0±0.6	2.6

for a further 24 h. An equal number of matched control fish were similarly handled, and injected only with fish physiological saline.

Hourly occupied temperatures were tabulated for the 24-hour periods before and after injection of each fish. The mean occupied temperatures were calculated, as were grand means (means of means) for each species and for all the test fish (Table 1). All bacteria-injected fish showed a significant increase (*t* test, 0.05) in preferred temperature: mean temperature increase (ΔT) was 2.6°C for all test fish, 2.7°C for the bluegills and 2.1°C for the bass. The controls showed no increase.

We conclude that fish exhibit a behavioural fever, as do lizards, under the influence of bacterial pyrogens. This is probably due to a direct influence on the hypothalamic thermoregulatory centre, although direct evidence for this mechanism in fish awaits further neurophysiological study. Our data support the hypothesis that the neural mechanism for the control of thermoregulation, in the preoptic hypothalamus, had a common origin early in the evolutionary history of vertebrates<sup>1,7-11</sup>. Fever as an adaptive response to infection<sup>2-4</sup> may have similarly had its origin early in vertebrate history, even before the evolution of a terrestrial mode of life.

This work was partially supported by the Commonwealth Campus Scholarly Activity Fund from The Pennsylvania State University to W.W.R. We thank Dr Hans Rothenbacher for providing the *Aeromonas* culture.

## Gravity as the sole navigational aid to the newborn quokka

ALTHOUGH there is general agreement on the sequence of events at birth for several marsupial species<sup>1</sup>, it is still not known how the newborn joey navigates on its journey from the mother's cloaca to her pouch. Frith and Calaby<sup>2</sup> have postulated that, at birth, the red kangaroo (*Megaleia rufa*) "has large nostrils and presumably a well developed sense of smell which probably plays a major part in its location of the pouch". On the other hand, Hartman<sup>3</sup> has suggested that the newborn opossum (*Didelphis virginiana*) was "negatively geotropic" though he has now modified this view considerably<sup>4</sup>, as histological studies have revealed that the vestibular apparatus of the newborn animal is undifferentiated and therefore non-functional<sup>5,6</sup>. To investigate whether one of these mechanisms<sup>2,4</sup> could account for the behaviour of the newborn quokka (*Setonix brachyurus*) we have observed parturition in this macropodid marsupial.

Female quokkas mate soon after giving birth and such animals often develop a blastocyst in the state of diapause in the uterus. Removal of the pouch young causes this blastocyst to resume development so that a birth occurs about 26 days later<sup>7</sup>. In March 1974 and 1975 pouch young were removed from a total of 14 quokkas obtained from a wild population on Rottnest Island, Western Australia. The animals were transferred to a controlled environment 22 d later, then observed continuously. In all, seven animals gave birth; four births were seen and one was recorded in detail on videotape.

Our observations of these births confirm those of Tyndale-Biscoe<sup>8</sup>. In spite of intensive antepartum grooming of the pouch and cloacal region, there is no evidence of a path made by the mother to facilitate the passage of the joey from the cloaca to the pouch. The mother's position during birth was such that the abdominal wall was almost vertical and the lower lip of the pouch pouted outwards. Observation of the actual entry of the joey into the pouch was difficult because of the stance of the mother but on one occasion the joey seemed merely to tumble in over the lip.

After a birth in 1974 the joey was retrieved as soon as it had reached the pouch. The mother was then held vertically, head up, and the joey was placed on the upper (anterior) lip of the pouch. During the next 3 min it climbed about 3 cm upwards away from the pouch. The mother was then turned upside down. The joey faltered and eventually turned completely around so that its head was again pointed upwards, towards the pouch. It then became entangled in the mother's fur and made no progress. When the mother was returned to the head up position the joey reversed its direction again and progressed away from the pouch. It was then removed from the mother's chest and replaced near the cloaca, whence it succeeded in making a second journey to the pouch.

On the occasion of the videotaped birth in 1975 the mother was removed from her cage and held almost vertical, with her right side slightly lower than her left, while the newborn joey was still making its initial journey to the pouch. This led to its direction changing slightly so that it passed by the pouch; it did not falter but continued to climb to the mother's chest, leaving a distinct path, about 1 cm deep, in the fur. The mother was then turned to the head down position and, as before, the joey slowly turned around, this time without becoming entangled in the fur,

and made progress back towards the pouch. The joey was not handled during this experiment.

These observations suggested that the newborn quokka has a righting reflex; we found that it could also turn over when placed on its back. But older pouch young, up to the age of 65-70 d, no longer retain this ability, and histological sections through the head of a newborn joey support the conclusion that the vestibular apparatus is undifferentiated<sup>5,6</sup>. It seems to us that this transient righting reflex could be mediated by muscle stretch receptors, particularly in the neck.

These experiments confirm the negative geotropism of the newborn quokka and reveal no other mechanism directing its movement towards the pouch. In the second experiment, in particular, the joey passed within 1 cm of the pouch opening without hesitating in its upward climb and it is clear that chemotaxis can be discounted in this case.

## Impaired acquisition of a passive avoidance response after lesions induced in the locus coeruleus by 6-OH-dopamine

Crow<sup>1</sup> and Kety<sup>2</sup> have advanced the hypothesis that the fine network of noradrenaline-containing nerve terminals which innervates the cerebral cortex<sup>3</sup> is a necessary component of the mechanism of learning. In particular, it is suggested that these neurones deliver a "results of action"<sup>4</sup> signal which registers the successful outcome of a particular behavioural sequence. The noradrenaline released in the cortex is believed to interact with a transient synaptic change resulting from recent neural activity (the 'short-term trace'), to initiate the long term synaptic changes presumed to underlie learning. Various authors have suggested the existence of such a "confirming reaction"<sup>5</sup>, "results of action"<sup>6</sup>, or "now print"<sup>7</sup> mechanism. The diffuse distribution of noradrenergic terminals in the cerebral cortex would allow this system to deliver a generalised message of the type required. Ungerstedt<sup>7</sup> has demonstrated histochemically that the cortical noradrenergic terminals originate from cell bodies of the nucleus locus coeruleus in the dorsal pontine tegmentum, and this has been confirmed in biochemical studies<sup>8,9</sup>. The concept of the coeruleo-cortical noradrenergic system as a reinforcement pathway is supported by the observation that rats with electrodes in the region of the locus coeruleus can be trained to self stimulate<sup>10,11</sup> and this behaviour is accompanied by increased noradrenaline turnover in the ipsilateral cortex<sup>12</sup>.

The prediction that bilateral lesions of the locus coeruleus would impair learning capacity<sup>1,2,13</sup> has been tested in a runway<sup>8</sup> and a two-choice discrimination learning test<sup>14</sup>.

Since moderately extensive lesions of the locus coeruleus did not impair acquisition in this latter task it has been argued<sup>14</sup> that the apparent impairment in runway performance either does not constitute a learning deficit, or is not representative of a general impairment of learning capacity. By contrast, in an avoidance situation, Stein *et al.*<sup>15</sup> have shown that the learning deficit which can be demonstrated following administration of diethyldithiocarbamate (DDC), a drug which depletes noradrenaline stores by inhibiting dopamine- $\beta$ -hydroxylase, can be reversed by intraventricular administration of noradrenaline. These findings suggest that the integrity of certain central noradrenergic pathways is necessary for learning in this situation. Here we have investigated whether this deficit in avoidance learning is a consequence of impaired transmission in the coeruleo-cortical noradrenergic system.

Seventy-nine female Sprague-Dawley rats (initial weight 150 g) were divided into an untreated control group ( $n=24$ ), a group in which the coeruleo-cortical system was damaged by a stereotaxic injection of 6-OH-dopamine (6-OH-DA) (16  $\mu$ g in 4  $\mu$ l, bilaterally over 4 min) delivered through burr holes just anterior to the locus coeruleus 3 weeks before testing ( $n=23$ ); a group with burr holes but no injection ( $n=23$ ); and a group treated with DDC 300 mg  $\text{kg}^{-1}$  between the first and the second trials of the training procedure ( $n=9$ ). The time taken for each animal to step off a platform on to the electrifiable grid floor of the test chamber was recorded by contact switches in each of five test sessions. The first two trials were separated by 2 h, and after 1 h all animals were given either DDC or saline subcutaneously (Fig. 1). On the third trial, animals were shocked (4 mA, scrambled across the grid, for 3 s) as they stepped down, and on the fourth (1 min later) and fifth (3 d later) trials the effects of this experience on the animals' subsequent step-down time was tested. With this experimental design it is likely that dopamine- $\beta$ -hydroxylase inhibition in the DDC-treated group is present at the time

Fig. 1 The experimental design DDC 300 mg  $\text{kg}^{-1}$  by subcutaneous injection.

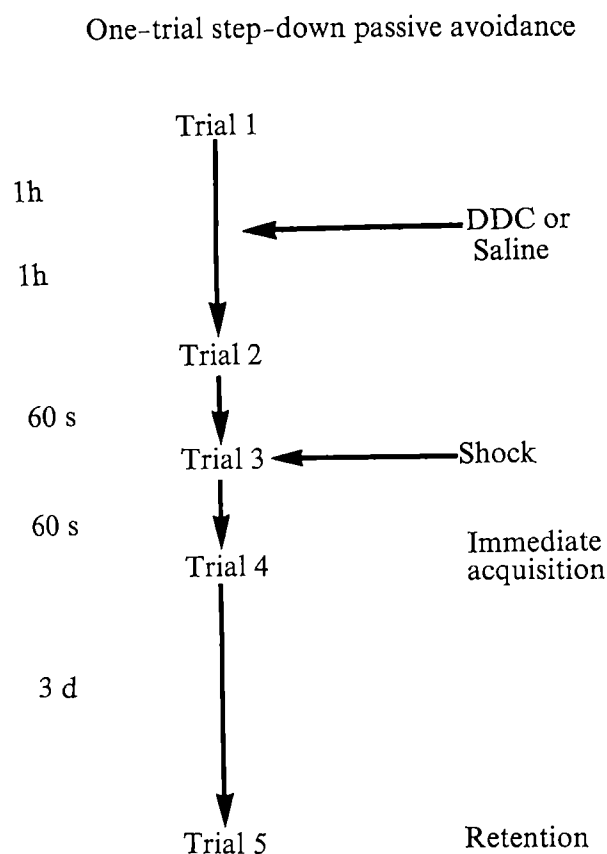

Fig. 2 Mean step-down times (s) on trials 1-5 in groups of rats treated with 6-OH-DA 3 weeks before testing (x), and DDC (300 mg  $\text{kg}^{-1}$ ) between trials 1 and 2 (●), compared with untreated controls (□) and a group of rats who had burr holes drilled in the skull (○). All animals received foot shock on stepping down on to an electrifiable grid floor on trial 3. The change in step-down time between trials 3 and 4 ( $t_4-t_3$  in Table 1) represents the effects of shock on the animal's behaviour after 60 s (immediate acquisition). The comparison between trials 4 and 5 ( $t_4-t_5$ ) is an index of the animal's ability to retain the avoidance response after 3 d (retention). Bars indicate s.e.m.

of the learning experience (trial 3) and at the time of the immediate acquisition test (trial 4), but is not present on trial 5 (ref. 15).

Both the 6-OH-DA- and DDC-treated rats showed normal immediate acquisition of the avoidance response as assessed by an increase in step-down time between trials 3 and 4 (Fig. 2 and  $t_4-t_3$  in Table 1). Neither group differed significantly from the untreated controls, although the 6-OH-DA-treated group somewhat surprisingly performed significantly better than the burr-hole group (Table 1). Compared with both the untreated controls and the burr-hole group, the two experimental groups showed a failure of retention after 3 d, as shown by the differences in step-down time between trials 4 and 5 ( $t_4-t_5$  in Table 1). Compared with the two control groups, the 6-OH-DA-lesioned and DDC-treated rats both showed a significant ( $P<0.01$ ) decrease ( $t_4-t_5$  in Table 1) in time spent on the platform. Activity levels measured in an Animex instrument (LKB Farad) showed no significant differences between the 6-OH-DA-lesioned rats, the group with burr holes and the controls (Table 2). Subsequently, the brains of the rats in the 6-OH-DA-lesioned group were removed and the cortices dissected out and assayed for noradrenaline using a spectrofluorimetric technique. The mean cortical noradrenaline level in the 6-OH-DA-lesioned group ( $n=23$ ) was  $93 \pm 12.6$  (s.e.m.) ng  $\text{g}^{-1}$ , approximately 15% of that present in a sample of the control group,  $611 \pm 68$  ng  $\text{g}^{-1}$  ( $n=4$ ).

Since immediate acquisition in these rats is unimpaired

Table 1 The increase ( $t_4-t_3$ ) in step-down time immediately following foot shock on trial 3 (immediate acquisition) and the change ( $t_4-t_5$ ) in step-down time after a subsequent 3-d interval (retention)

	<i>n</i>	Immediate acquisition $t_4-t_3$ (s $\pm$ 1 s.e.m.)	Retention $t_4-t_5$
Untreated controls	24	63.7 $\pm$ 9.5	5.2 $\pm$ 10.2
Burr holes only	23	43.6 $\pm$ 9.7	-0.9 $\pm$ 16.6
6-OH-DA lesions	23	83.2 $\pm$ 9.0†	58.5 $\pm$ 10.4*
DDC 300 mg $\text{kg}^{-1}$	9	63.6 $\pm$ 12.2	60.8 $\pm$ 17.0*

\*  $P < 0.01$  compared with untreated controls and burr-hole group  
†  $P < 0.01$  compared with burr-hole group.

**Table 2** Small and large movements measured in an Animex instrument over a period of 5 min

	<i>n</i>	Controls 24	Burr holes 23	6-OH-DA lesioned 23
Movements	Large	54±4	64±6	55±6
	Small	154±6	162±10	166±9

it seems unlikely that the deficit is due to impaired sensory or motor capacity; more probably it represents a defect in the capacity to form a long lasting record of previous experience. Moreover, since an identical impairment is observed after both administration, at the time of the learning experience, of drugs known to impair the synthesis of noradrenaline and after neurochemical lesions of a central noradrenaline-containing pathway, it seems likely, as Stein *et al.*<sup>15</sup> suggest, that the deficit results from impaired central noradrenergic transmission at a critical stage in the learning process. Our results are compatible with the hypothesis that the system of noradrenergic neurones arising from the locus coeruleus is necessary for initiating the transition from a short to a long term memory trace, and that the integrity of this system is necessary for this transition to occur, at least in an avoidance learning situation.

We are grateful to Ann Smith and A. Longden for technical assistance.

## Generalisation of the Hardy-Weinberg law

THE distribution of genotypes  $q^2aa + 2qpaA + p^2AA$ , commonly called the Hardy-Weinberg law, has been recognised at least since 1908. It gives the frequencies of genotypes in a randomly mating population with respect to a single locus maintaining two alleles  $a$  and  $A$  with respective frequencies  $q$  and  $p$ . A generalisation given in 1922 by Wright and discussed in his book<sup>1</sup> gives the distribution

$$(q^2 + Fqp)aa + 2(1-F)qpaA + (p^2 + Fqp)AA$$

where  $F$ , the "fixation index" is the correlation between pairs of gametes uniting to form zygotes.

Here we point out that a distribution of the same form as Wright's is maintained in equilibrium by a pattern of assortative mating devised in 1918 by Fisher<sup>2</sup> and elaborated in 1939 and 1948 by Malécot<sup>3</sup>.

Fisher was concerned with continuously varying characters

and took as his datum that the correlation between mates could be described by a bivariate normal distribution with coefficient  $\mu$ . He found that if females with standardised value  $x$  occur in the population with frequency  $N$  and males with value  $y$  have frequency  $M$ , then  $x$ - $y$  pairs occur with frequency  $MN(1 + \mu xy)$ . In populations with random mating the corresponding frequency is  $MN$ , so that, if  $\mu > 0$ , Fisher's assumption implies a higher frequency of pairs when both partners have above average or below average values, and lower when one has above and the other below average values, compared with the randomly mating population.

Malécot<sup>4</sup> started from this implication and derived the distribution for one locus,  $f_0 = (q^2 + \lambda qp)$ ,  $f_1 = 2(1 - \lambda)qp$ ,  $f_2 = (p^2 + \lambda qp)$ , which is of the same form as Wright's, the only difference being the replacement of Wright's fixation index by Malécot's "constant of homogamy"  $\lambda$ . If the genotypes are given arbitrary values 0, 1, 2, respectively, the mean and variance of Malécot's distribution are  $m = 2p$  and  $s^2 = 2(1 + \lambda)qp$ , respectively. Also, the deviations from the mean of the genotypes are  $d_0 = -2p$ ,  $d_1 = q - p$ , and  $d_2 = 2q$ , respectively.

Consider a population which starts with Malécot's distribution in both sexes and assume that the frequencies of  $x$ - $y$  mating pairs are given by

$$f_{xy} = f_x f_y (1 + \mu d_x d_y / s^2)$$

where  $x = 0, 1, 2$  and  $y = 0, 1, 2$ . Then it can be shown that, given the usual Mendelian assumptions, the distribution of genotypes among offspring is again that of Malécot, provided that  $\mu$  and  $\lambda$  are related by  $\mu = 2\lambda/(1 + \lambda)$ . Furthermore, it is found that, for all mating frequencies to be non-negative,  $\mu$  must be restricted to the range  $(1 - 1/p^2, 1)$  if  $q \leq p$ , and  $(1 - 1/q^2, 1)$ , if  $q > p$ .

Thanks are due to Professor G. Malécot for advice regarding the preparation of this paper.

## Cross-modal transfer in the chimpanzee

TASKS of cross-modal performance assess the capacity to recognise stimulus-objects with one of the senses when they have previously been experienced only with another. In a number of recent publications<sup>1-3</sup>, it has been shown that apes succeed at such tasks, in marked contrast to the negative or weak effects previously found for monkeys. The training procedures used with the apes were, however, new<sup>1</sup>, and had not been tried with monkeys, so that it remained possible that monkeys would perform as well as apes with these procedures<sup>4-5</sup>. Monkeys have been shown capable of cross-modal performance in two different methods of training (ref. 6, and M. J. Jarvis and G. Ettlinger, unpublished) one of which was designed to follow the principles used successfully with apes. We here describe the performance of three chimpanzees on cross-modal tasks of a kind which have in the past not yielded positive results with monkeys: our findings with the chimpanzees are unclear, or at least not certainly positive.

We assessed cross-modal transfer in three male chimpanzees (*Pan troglodytes verus*) weighing 16-20 kg, using procedures which have been described in earlier reports on monkeys<sup>7-9</sup>. The sequence of training is shown in Table 1. After preliminary

adaptation to making two-choice simultaneous discriminations by pushing lids of food boxes in a WGTA in the dark and light, the apes were trained on five transfer tasks. Each task was presented to one sense until the animal reached a standard level of performance (45 correct responses in 50 successive trials for the initial four tasks, 160 correct responses in 200 trials for task 5); and then the same pair of objects was presented to the other sense, either with the same object rewarded as before (non-reversal) or with the previously unrewarded object now rewarded (reversal). In tactile training the objects were palpated directly in total darkness. Performance was monitored with a video system sensitive to infrared light. For visual training the objects were mounted on similar lids of food boxes, but a small handle was put on the lid in front of the object. These handles had to be used in the preliminary colour discrimination (as the colours were flat papers) and subsequently the handles were used (instead of the objects) for pushing the lids on all visual trials except three. The test objects are shown in Fig. 1; 40–60 trials were given daily, five days each week, with two peanuts as reward for a correct response. The poor learning scores may reflect concurrent daily training in three other investigations: after completing its training for this experiment early each morning each ape was later trained on the same day on memory, sorting and cross-modal recognition tasks. (Observations did not suggest that  $\approx 200$  trials were too many for each animal on each day. We prefer, with Warren<sup>10</sup>, to suppose that an ape does not learn more readily than a monkey—and may learn more slowly.)

The learning scores are shown in Table 1. If the animal failed to relearn within 300 trials in the second sense, training was discontinued. Cross-modal transfer could become manifest in either (1) higher learning scores in the second sense on tasks involving reversal of reward than on non-reversal tasks; (2) lower savings scores for the second sense at reversal rather than non-reversal tasks, and/or (3) a greater number of errors in the initial ten trials in the second sense for reversal than non-reversal tasks. The mean learning scores in the second modality

**Fig. 1** Stimulus objects used for the visual versions of five transfer tasks. The objects were painted silver and set back on the lids of the food container behind small handles. The handles were used by the apes to push the lids so that no tactile information was gained during visual training in the light. For the tactile versions identical objects were painted matt black and fixed closer to the animal on another set of lids. The animals touched the objects directly to push the lids in the dark, and never gained visual experience of the objects. The tasks are identified in Table 1.

are 115 trials for 8 reversal and 120 trials for 6 non-reversal tasks. The mean savings are calculated from

$$\frac{1^{\text{st}} \text{ hand} - 2^{\text{nd}} \text{ hand}}{1^{\text{st}} \text{ hand} + 2^{\text{nd}} \text{ hand}}$$

to be  $-18.5$  for 8 reversal and  $+7.2$  for 6 non-reversal tasks. The mean errors in the first ten trials of the second modality are 6.4 errors for 8 reversal and 4.5 for 6 non-reversal tasks. After training on the transfer task 5 the procedure of Moffett and Ettlinger<sup>8</sup> was adopted for Algie and Blue: the apes were given 80 trials at random in the light and dark with the opposite orientations rewarded exactly as during learning in each modality (that is, choice of sagittal rewarded in the dark and of coronal in the light for Algie). During these interleaved visual and tactile trials the animals made 11 and 15 errors, representing the same level of performance as achieved during learning within one modality.

The findings with these three chimpanzees provide no clear evidence of cross-modal transfer. Our other chimpanzees are to be tested exactly as those described in this report but only after they have received prolonged training for cross-modal recognition according to the procedure of Jarvis and Ettlinger (unpublished). The expectation is that they will then give evidence of good cross-modal transfer. Such a finding would, in agreement with other work<sup>1</sup>, indicate that the chimpanzee can indeed attain cross-modal performance as a consequence of lengthy training. This is, however, also true for the monkey (Jarvis and Ettlinger, unpublished). Moreover, with the method of Cowey and Weiskrantz<sup>9</sup> monkeys and chimpanzees<sup>11</sup> can additionally attain unidirectional cross-modal recognition without lengthy training. We therefore conclude that it remains to be shown whether important differences exist between the cross-modal capacities of apes and monkeys. The present experiment emphasises the importance of testing different species in truly comparable conditions.

## Novel surface polymer changes in development of *Myxococcus* spp.

THE Myxobacteriaceae are unique among prokaryotes in their development cycle. Vegetative cells are Gram-negative bacilli which undergo binary fission as in other prokaryotes; alternatively, the cells can aggregate on solid surfaces to form fruiting bodies in which the bacteria undergo conversion to myxospores. In *Myxococcus xanthus* and related species a simple fruiting body is formed in which spherical myxospores are surrounded by extracellular polysaccharide slime<sup>1</sup>. In at least one strain of *M. xanthus*, synchronous myxospore formation can be obtained in liquid culture through induction with glycerol and other agents<sup>2</sup>. The entire bacillus undergoes conversion to the myxospore form; there is no apparent loss of cell material such as is observed in the morphogenesis of Gram-positive bacilli to endospores at the expense of cell wall and surface material shed on emergence of the mature spore. The fate of the *Myxococcus* surface polymers is thus of particular interest.

*M. xanthus* has been the subject of numerous cytological studies<sup>3,4</sup> which have indicated the formation of a thick extracellular coat together with a vesicular structure contained between this coat and the cytoplasmic membrane. The structural polymer, peptidoglycan, is present in cell walls of both bacilli and myxospores, although in a slightly modified form in the latter<sup>5</sup>. Both bacilli and myxospores are surrounded on solid media by extracellular polysaccharide which is of the same chemotype, and possibly identical, in bacillary cultures and in fruiting bodies<sup>6</sup>. We have now investigated the cell wall polysaccharides in bacilli and in myxospores, both those isolated from fruiting bodies and those obtained by glycerol induction. In particular, myxospores have been examined to determine whether they contained lipopolysaccharide.

Bacteria used were *M. xanthus* strain FB (Professor M. Dworkin, University of Minnesota) and a strain isolated from local soil (designated S). Strain FB underwent dispersed growth in liquid media and was inducible to myxospores by glycerol; strain S gave granular growth and was only poorly inducible to myxospores. The microanalytical procedures used have been described previously<sup>6,7</sup>, except that acid hydrolysates were neutralised with Ba(OH)<sub>2</sub>, separated into neutral and hexosamine fractions by preparative paper electrophoresis in pyridinium acetate buffer (pH 5.3) and analysed after elution. This procedure was

adopted because of the difficulty in obtaining uniform suspensions of myxospores and the use of hydrolysates of whole cells.

Lipopolysaccharide was present in the bacillary forms of the two strains and was extractable by the hot phenol procedure (65 °C, 5 min). It could then be deposited by ultracentrifugation at 100,000g for 4 h. Attempts to obtain lipopolysaccharide from myxospores of either strain were unsuccessful, although the bacilli had yielded 0.7–1.1% of their dry weight as sedimentable lipopolysaccharide. No carbohydrate-containing material was present in the phenol phase after extraction of myxospores as would be expected if the polymer had become more hydrophobic through loss of polysaccharide side chains<sup>8</sup>. As myxospores cannot be disintegrated by ultrasonic treatment or other readily available methods<sup>9</sup> an alternative extraction procedure was required to obtain the polysaccharides known to be present<sup>10</sup>. The composition of these polysaccharides could be ascertained by analysis of hydrolysates of whole myxospores, as the only other monosaccharides known to be present are *N*-acetylglucosamine and *N*-acetylmuramic acid derived from peptidoglycan. The extraction procedure used by Freeman<sup>11</sup> to obtain side chain material from *Salmonella* lipopolysaccharides, 0.1 M acetic acid at 100 °C for 12 h, yielded carbohydrate-containing material from both bacilli and myxospores. From 95 mg freeze-dried myxospores of strain FB, 9 mg non-diffusible material was solubilised by the acetic acid treatment; the carbohydrate content was approximately 65%. Yields from strain S myxospores isolated from fruiting bodies were slightly lower. The carbohydrate composition of the lipopolysaccharides, acetic acid extracts and whole myxospores was compared by analysis and paper chromatography of hydrolysates (Table 1). Slight differences between the lipopolysaccharide composition found for strain FB and the results reported<sup>7</sup> are almost certainly attributable to the improved accuracy of the analytical procedures when hydrolysates were freed from salts and other non-carbohydrate material by electrophoresis.

Chromatograms indicated that in strain FB, mannose present in the lipopolysaccharide had almost all disappeared from myxospores, while the ratio of glucose and galactosamine to glucosamine increased greatly in the myxospores. No appreciable differences were found between myxospores of this strain induced with glycerol and those obtained from fruiting bodies. Strain S lipopolysaccharide contained two sugars, mannose and galactose, which were almost entirely lost from myxospores; again there was an apparent increase in the glucose and galactosamine content. These observations were confirmed by analysis.

The two *Myxococcus* strains examined lack any of the more unusual sugars reported in the lipopolysaccharides of other Gram-negative bacteria—heptose, 3-*O*-methyl xylose and dideoxyhexoses are absent. Both, however, contain 2-keto-3-deoxyoctonic acid in their lipopolysaccharides<sup>7</sup>. Attempts to identify this compound in hydrolysates of

Table 1 Composition of polysaccharide preparations from *Myxococcus* strains FB and S

Strain	Preparation	Mannose	Glucose	Galactose	Glucosamine	Galactosamine	Ribose
FB	Lipopolysaccharide	15.3	31.2	0.3	18.9	29.0	5.1

\*Glycerol induced; †Isolated from fruiting bodies.

Monosaccharide values are expressed as % total carbohydrate recovered after electrophoresis and elution.

myxospores were unsuccessful although it was identified on electrophoretic separation of the lipopolysaccharide hydrolysates. Although not conclusive in itself, this result, together with the loss of other monosaccharides, suggests that a hitherto unrecognised feature of the formation of myxospores from the bacillary forms of *M. xanthus* (and a phenomenon not previously reported for Gram-negative bacteria) is the complete loss from the wall of the polysaccharide portion of the lipopolysaccharide. The fate of the lipid A portion has not yet been ascertained. An analogy can thus be found to the loss of teichoic acid in bacterial endospore formation<sup>12</sup>, except that the bacillary wall is not lost during myxospore development. Instead, there is an apparently selective rejection of the polysaccharide component of the lipopolysaccharide. It is not clear whether this is attributable to enzymatic removal or to ejection to make way for the new glucose- and galactosamine-containing polymer identified by Johnson and White<sup>10</sup>. Preliminary results suggest that replacement of lipopolysaccharide by a new polymer also occurs during myxospore formation in other fruiting species of Myxobacteria.

## Use of ionophore A23187 to measure cytoplasmic Ca buffering and activation of the Ca pump by internal Ca

DURING the formation of the mature mammalian erythrocyte, the reticulocyte sheds its nucleus, endoplasmic reticulum and mitochondria leaving a featureless cytoplasm with a high haemoglobin content surrounded by a plasma membrane. All Ca-accumulating organelles are lost and the mature red cell is maintained virtually Ca-free throughout its life<sup>1</sup> by the low Ca permeability of its membrane<sup>2</sup> perhaps aided by a powerful Ca-extrusion pump<sup>3</sup>. Most of our knowledge of Ca transport in red cells comes from studies with resealed ghosts, but in this preparation the results are often affected by alterations to the membrane and metabolism of the cell<sup>2-4</sup>. The main difficulty of using intact fresh cells in physiological conditions has been the impossibility of increasing their Ca content in a controlled way and of assessing the fraction of Ca which is ionised. Using a divalent-cation ionophore, A23187 (ref. 5), however, we have overcome these difficulties and found that cytoplasmic Ca buffering occurs as if the cell had a single large-capacity, low-affinity Ca buffer and that there are two Ca-translocating sites of equal affinity at the internal surface of the Ca pump.

Preliminary experiments showed that in the red cell the ionophore selectively increases the Ca and Mg fluxes without affecting directly the Na and K fluxes, in agreement with its action in other systems<sup>6</sup>. The incorporation of the ionophore into the red cell membrane induces a large Ca leak. In these conditions, the rate of change of the total Ca concentration in the cell ( $\mu\text{mol per l cells per h}$ ) is given by

$$d\text{Ca}_i^T/dt = P(r^2\text{Ca}_o - \alpha\text{Ca}_i^T) - \phi \quad (1)$$

where  $P$  represents the ionophore-induced leak permeability

for Ca ( $\text{h}^{-1}$ );  $r^2$  is the Donnan distribution ratio for divalent ions at equilibrium and is related to the membrane potential ( $V_m$ ) by the expression  $r^2 = \exp(-2FV_m/RT)$ ;  $\alpha$  is the fraction of ionised Ca inside the cell;  $\text{Ca}_o$  is the concentration of ionised Ca in the medium and  $\phi$  is the Ca extrusion rate through the Ca pump ( $\mu\text{mol per l cells per h}$ ). The maintenance of steady states for  $\text{Ca}_i^T$  (see Fig. 1) suggests that the Ca pump remains saturated with ATP for the duration of our experiments. Following Schatzmann<sup>3</sup> the pump-flux term can therefore be expressed as

$$\phi = \phi_m[\alpha\text{Ca}_i^T/(\alpha\text{Ca}_i^T + K)]$$

where  $\phi_m$  represents the maximum Ca pumping rate and  $K$  is the Ca dissociation constant at the internal surface of the pump.

Red cells from fresh blood or from 3-4-d-old bank blood were washed 3 times with about ten volumes of ice-cold solution containing NaCl, 75 mM; KCl, 75 mM; Tris-Cl (pH 7.5 at 37 °C), 10 mM and Tris-EGTA (1,2-Di(2-aminoethoxy) ethane-NNN'-tetraacetic acid), 0.1 mM and 4 times more with the same solution without Tris-EGTA. After the washes the cells were packed at 2,000g for 5 min and the supernatant disposed of. At  $t = 0$ , 0.25 ml of packed cells were added to 2 ml of a medium at 37 °C stirred magnetically and containing: NaCl, 75 mM; KCl, 75 mM; Tris-HCl (pH 7.5 at 37 °C), 10 mM;  $\text{MgCl}_2$ , 1-2.33 mM; Inosine, 10 mM, 5  $\mu\text{Ci}$  of  $^{45}\text{Ca}$  and varying amounts of  $\text{CaCl}_2$ . This particular K concentration was used to minimise the effect which a Ca-induced increase in K permeability<sup>6</sup> might have had on the membrane potential and, therefore, on  $r$ . Samples were withdrawn from this cell suspension at suitable time intervals and processed as detailed in the legend of Fig. 1.

Figure 1 shows two representative time curves at initial concentrations of  $\text{Ca}_o$  of 93.2 and 1,000  $\mu\text{M}$ . In this experiment, at 93.2  $\mu\text{M}$   $\text{Ca}_o$  and the lower concentrations, the uptake of Ca at 30 s went through a maximum considerably larger than the steady-state value, whereas at higher  $\text{Ca}_o$  the kinetic pattern followed was that represented by the 1,000- $\mu\text{M}$  curve. The transient peak was never observed in ATP-depleted cells<sup>7</sup> or at higher external Ca concentrations in fed cells. Its dependence on the metabolic state of the cell suggests an initial inactivity of the Ca pump. Successive additions of ionophore to fed cells in the presence of lower Ca concentrations, however, always elicits a transient peak response. A possible explanation of these peaks is that initially only a fraction of the cells takes up all the ionophore, thus behaving like the high-ionophore cells in Fig. 2. As the ionophore becomes more homogeneously distributed, Ca is pumped out from these cells and a final steady state with a lower average Ca content is achieved. If  $^{45}\text{Ca}$  is added during steady state to cells containing enough Ca to saturate the pump, the final  $^{45}\text{Ca}$  distribution is the same as in controls with  $^{45}\text{Ca}$  present from the beginning but is approached exponentially without any maxima. In depleted cells, the steady-state distribution of Ca was unaffected by further additions of ionophore, but in fed cells this was true only for very high initial ionophore concentrations (above 100  $\mu\text{mol per l cells}$ ).

The use of  $\alpha$  in equation (1) to describe the buffering of Ca by the red cell involves a number of simplifying assumptions which require consideration. In the general case for  $n$  intracellular buffers the relation between total and free Ca is described by

$$\text{Ca}_i^T = \text{Ca}_i^{2+}[(V_w/V_c) + \sum_{i=1}^n \{B_i/(K_i + \text{Ca}_i^{2+})\}] \quad (2)$$

where  $V_w$  is the volume of cell water per litre of cells ( $V_c$ );  $B_i$ , the total concentration of the  $i$ th buffer, and  $K_i$  the dissociation constant between Ca and this buffer.

In ATP-depleted cells<sup>7</sup>, the ionophore induced the red cell

membrane to act like a "dialysis bag" for Ca. The equilibrium distribution of Ca as a function of external Ca showed that Ca buffering can be satisfactorily described assuming the cells have a single large-capacity low-affinity Ca buffer in agreement with earlier results obtained with cell lysates<sup>3</sup>. In this case, equation (2) becomes

$$Ca_i^T = Ca_i^{2+}[(V_w/V_c) + B/(K_B + Ca_i^{2+})]$$

If  $Ca_i^{2+} \ll K_B$  then

$$Ca_i^T = Ca_i^{2+}[(V_w/V_c) + (B/K_B)]$$

and

$$\alpha = [(V_w/V_c) + (B/K_B)]^{-1}$$

The use of  $V_w/V_c$  already allows for the fact that while  $Ca_i^T$  is expressed per litre of cells,  $Ca_i^{2+}$  represents the actual concentration of ionised Ca per litre of cell water.

In fresh cells, the buffering capacity was estimated from the slope of the curve relating the steady-state internal Ca concentration ( $Ca_i^T$ ) with the external free Ca concentration ( $Ca_o$ )

**Fig. 1** Ca content of cells as a function of time at two different external Ca concentrations. At the times indicated 0.1-ml samples of the cell suspension were placed in 1.5-ml Eppendorf centrifuge tubes containing 0.4 ml *n*-butyl-phthalate (BDH, density 1.042–1.045) and 0.9 ml of the initial washing medium but with 5 mM Tris-EGTA, all at 0–1 °C. Each sample was centrifuged immediately for 10 s at 12,000g in an Eppendorf centrifuge model 3200. The cells formed a compact pellet at the bottom of the oil layer and the aqueous supernatant remained on top. The whole procedure from sampling to cell separation took about 20 s. The supernatant, including the oil, was sucked off and the walls of the tube cleaned and dried with cotton swabs. The cells were lysed in 0.5 ml of distilled water, the proteins precipitated with 5% TCA and aliquots used for counting. Samples for total activity and haemoglobin were taken at the end of each run. The extracellular activity trapped in the cellular pellet was estimated using <sup>45</sup>Ca in the presence of a large excess of Tris-EGTA. The cells were added at  $t = 0$  and the ionophore was added after the second sample, at  $t = 3.5$  min in 10 μl of absolute ethanol to give a final concentration of 10 μmol per l cells (assuming complete partitioning of the ionophore into the cells). Ordinates: Ca content of cells (in μmol per l original cell volume). Note the fortyfold difference in scale between left and right ordinates corresponding to the curves at low and high external Ca concentration, respectively. ○, Initial external Ca concentration, 93.2 μM, final steady state concentration, 90.7 μM; ●, initial external Ca concentration: 1,000 μM, final steady state concentration, 740 μM. Haematocrit, 8.9%. The increased frequency of sampling during the steady state is due to the fact that <sup>42</sup>K was added at  $t = 15.5$  min to measure simultaneously the K influx associated with each particular steady Ca level. (The results on the relationship between potassium permeability and the internal free Ca concentration in the intact fresh red cell will be published elsewhere.) The curves represent the kinetic patterns obtained with eleven concentrations of external Ca tested (see text).

**Fig. 2** Total Ca content of red cells as a function of external Ca concentration during steady state. In this experiment we used three ionophore concentrations: ○, 100 μmol per l cells,  $I = 100$ ; ●, 25 μmol per l cells,  $I = 25$ ; and △, 6.3 μmol per l cells,  $I = 6.3$ . Assuming complete partitioning of the ionophore into the cells, the highest concentration corresponds to about  $6 \times 10^8$  molecules per cell. If it is all partitioned into the red cell membrane, at the highest concentration there would be roughly one molecule of ionophore per 2,600 Å<sup>2</sup> of membrane which, with a molecular weight of 523 (ref. 5), will cover probably less than 0.5% of the cell surface. The value of  $\alpha$  in this experiment was 0.43 and it was unaffected by the concentration of ionophore used. It was assumed that  $r^2 = 2$  which corresponds to a steady-state membrane potential of about 10 mV.

when the Ca pump became saturated (see Fig. 2). When  $dCa_i^T/dt = 0$  (steady state) and  $\phi = \phi_m$  equation (1) becomes

$$Ca_i^T = (r^2/\alpha)Ca_o - (\phi_m/\alpha P) \quad (3)$$

This relation between  $Ca_i^T$  and  $Ca_o$  was shown to be valid over a wide range of ionophore and Ca concentrations (see Fig. 2). The value of  $\alpha$  varied from 0.3 to 0.5 among cells from different donors indicating that the fraction of ionised Ca represents between 30% and 50% of the total intracellular Ca concentration.

We then calculated the value of the dissociation constant for Ca at the internal pump site. At relatively low external Ca concentrations, the Ca pump is capable of maintaining large Ca gradients across the membrane during steady state (see Fig. 1), and in these conditions  $dCa_i^T/dt = 0$  and  $r^2Ca_o \gg \alpha Ca_i^T$ . Equation (1) can be rearranged to give

$$Ca_o = (\phi_m/r^2P)[\alpha Ca_i^T/(K + \alpha Ca_i^T)] \quad (4)$$

At similar external concentrations, equation (4) can be used to compare the measured value of  $\alpha Ca_i^T$  from different experiments and at different ionophore concentrations. If  $x$  and  $y$  represent the ionised Ca concentration ( $\alpha Ca_i^T$ ) obtained in two different

experiments, or at two different ionophore concentrations, then, equation (4) becomes

$$Ca_0 = C_1[x/(K+x)] = C_2[y/(K+y)] \quad (5)$$

where  $C_1$  and  $C_2$  represent the constant factor ( $\phi_m/r^2P$ ) for the two conditions that are being compared. Equation (5) can be rearranged to give

$$1/x = (C_1/C_2)(1/y) + [(C_1/C_2) - 1]/K \quad (6)$$

This equation predicts a linear relationship from which the value of  $K$  can be calculated. Figure 3 illustrates such a calculation and confirms the linear relation predicted by equation (6). The values of  $K$  obtained by this method varied between 0.73 and 1.02  $\mu\text{M}$ . Note that  $K$  calculated in this way is independent of the stoichiometry of transport, since it remains invariant if equation (5) were

$$C_1[x/(K+x)]^n = C_2[y/(K+y)]^n$$

provided that the different translocating sites have similar affinities.

This value of  $K$  was then used to plot  $(r^2Ca_0 - \alpha Ca_i^T)$  as a function of the pump saturation ratio  $[\alpha Ca_i^T/(K + \alpha Ca_i^T)]$  in all the conditions tested (Fig. 4). The linear relationship predicted by equation (1) was only confirmed when we used a stoichiometry of two translocating sites (see Fig. 4).

The slope of the curve in Fig. 4 (slope =  $\phi_m/P$ , equation (1)) could be used to estimate  $\phi_m$  if  $P$  were known. We can only obtain a rough estimate of  $P$  from the ratio between the  $\text{Ca}$  uptake at 30 s and  $r^2Ca_0$ . This gives values of  $P$  between 7 and 20  $\text{h}^{-1}$  which correspond to values of  $\phi_m$  of about 7 to 12  $\text{mmol per l cells per h}$ . This is considerably lower than the value expected at 37 °C from Schatzmann's data in resealed ghosts<sup>3</sup>.

This study introduces a general method by which the  $\text{Ca}$  concentration of the intact red cell can be varied in a controlled manner and its ionised fraction assessed. The method could also be applied to studies with  $\text{Mg}$  and opens new possibilities for the investigation of all the mechanisms involving divalent cations in the red cell. We report here a first application of this method. The binding of  $\text{Ca}$  at the internal  $\text{Ca}$ -pump surface can be described as taking place at two sites with similar dissociation constants around 1  $\mu\text{M}$ . This value closely agrees with a half-saturation concentration of 4  $\mu\text{M}$  or less for  $\text{Ca}$  translocation reported by Schatzmann<sup>3</sup>. Schatzmann, however, suggested a stoichiometry of one  $\text{Ca}$  per  $\text{ATP}$  hydrolysed and although we have not yet measured the hydrolysis of

Fig. 3 The relationship between the reciprocals of the steady-state intracellular concentrations of  $\text{Ca}$  at similar low external  $\text{Ca}$  levels of the two lower ionophore curves of Fig. 2. The continuous line corresponds to the equation

$$1/x = -0.179 + 0.577(1/y); K = 1.02$$

and is interpreted according to equation (6) in the text.

Fig. 4 The relationship between the steady-state value of  $(r^2Ca_0 - \alpha Ca_i^T)$  and the pump saturation ratio

$$P = [\alpha Ca_i^T / (K + \alpha Ca_i^T)]^n$$

according to equation (1). The value of  $K$  used was 1.02  $\mu\text{M}$  as obtained from Fig. 3. It can be seen that the straight line relationship predicted by equation (1) is obtained only if the square of the pump saturation ratio is used. This curve, corresponds to the curve obtained with the lowest ionophore concentration of Fig. 2. ●,  $n = 1$ ; ○,  $n = 2$ .

$\text{ATP}$  associated with  $\text{Ca}$  extrusion, our results firmly support a translocating stoichiometry of two  $\text{Ca}$  ions per pump cycle. This suggests a closer similarity with the sarcoplasmic reticulum pump<sup>7</sup>.

We thank The Lilly Research Centre Limited for a gift of the ionophore A23187 and The Wellcome Trust for funds. We also thank Dr D. Haydon and Professor I. M. Glynn for helpful comments and Mrs J. Gray for technical assistance.

## L-leucine, a specific inhibitor of a rare human placental alkaline phosphatase phenotype

FISHMAN *et al.* reported that human placental alkaline phosphatase (Regan isoenzyme) was found in the serum and tumour tissue of a patient with lung cancer<sup>1</sup>. Two electrophoretically different variant forms of Regan alkaline phosphatase with a greater sensitivity to inhibition by L-leucine have since been described: the 'Nagao isoenzyme'<sup>2</sup>

and a hepatoma-specific alkaline phosphatase<sup>3-5</sup>. Inglis *et al.*<sup>6</sup> reported that the L-leucine-sensitive Nagao isoenzyme found in some cancer patients closely resembled the 'D variant' of human placental alkaline phosphatase, a rare phenotype defined electrophoretically on starch gel which is found in less than 1% of the general population of pregnancies<sup>7</sup>. An example was reported of a pregnancy serum D-phenotype enzyme presumably of placental origin, confirmed by electrophoresis established as L-leucine-sensitive<sup>6</sup>. Most interesting was the occurrence of the variant at high frequency in the ovarian cancer patients surveyed<sup>6,8</sup>. To extend the observations of Inglis *et al.*, screening for the phosphatases in placenta was carried out, both to establish the frequency of the L-leucine-sensitive placental phenotypes (which should match the frequency of the electrophoretically defined D variant phenotypes) and to provide enough enzyme to enable purification and characterisation. Supply of cancer tissue is generally restrictive for this purpose.

Using a sample of ovarian cancer ascitic fluid containing the L-leucine-sensitive variant<sup>6</sup> as reference standard, we found nine placentae out of a total of 2,323 placentae screened (frequency 0.0039) which closely resembled the cancer patient enzyme in sensitivity to L-leucine. Normal placentae were obtained from St Margaret's Hospital, Dorchester, immediately after delivery and stored at -20 °C. Trophoblast tissue (5-15 g) was excised from each frozen placenta using a bone scalpel and homogenised with two volumes 0.9% saline per g tissue. The homogenate was centrifuged at 6,000g for 10 min and the supernatant diluted 1:100 with 0.01 M Tris-HCl-buffered saline, pH 8.3.

Alkaline phosphatase assay was carried out as described previously<sup>9</sup> using 18 mM phenyl phosphate as a substrate in 0.05 M sodium carbonate-bicarbonate buffer, pH 9.8, containing 10 mM MgCl<sub>2</sub>. To determine the optimum concentration of L-leucine, a partially purified enzyme preparation from an ovarian cancer patient was assayed for L-leucine inhibition. It was found to be 43% inhibited at a concentration of 0.5 mM L-leucine, using 0.5 mM D-leucine as a reference, whereas a non-variant placental enzyme was inhibited 8%. L-leucine (0.5 mM) was therefore used for screening, using the same concentration of D-leucine in the control sample. Each diluted sample (100 µl aliquots) was assayed for 30 min at 37 °C in 0.5 mM D- and L-leucine-containing substrate solutions. Inhibition of the 2,314 normal placentae was  $7.8 \pm 4.3\%$ , demonstrating that the common phenotypes of placental alkaline phosphatase<sup>7</sup> are not inhibited by L-leucine. Only the nine variants were outside the normal range (Table 1). Average inhibition profiles for the enzymes from nine individual variants and five normal placentae are shown as a function of L-leucine concentration. At all L-leucine concentrations tested, the variant enzymes were different from normal, this difference reaching a maximum of 40% at 0.5-2.0 mM L-leucine.

If the variant placentae are heterozygotes<sup>7</sup> consisting of 50% common phenotypic enzyme and 50% L-leucine-

Fig. 1 Average inhibition profiles in increasing concentrations of L-leucine: ○, variant enzyme (cv); ■, normal enzyme (cc); △, difference between inhibition of variant and normal enzymes (cv-cc); ▲, difference between twice the inhibition of heterozygous variant enzyme and normal enzyme (2cv-cc).

sensitive variant enzyme, it would be reasonable to estimate the inhibition of the L-leucine-sensitive moiety alone (vv) from the expression:

$$2cv - cc = vv$$

where cv represents the inhibition of the heterozygote made up of the common and variant phenotypes, cc the inhibition of placentae containing only the common phenotypes, and vv the inhibition expected for a homozygous variant enzyme. The approximation used here makes two assumptions: that the turnover number of the variant and common phenotypic enzymes for 18 mM phenyl phosphate are identical, and that there is no cooperativity in the inhibition of normal and variant enzyme in the heterozygote.

The result of this calculation for a full range of L-leucine concentrations is shown in Fig. 1 as the dotted line. The curve for vv reaches a level of 100% at about 1 mM L-leucine (the concentration at which the difference between the common and variant enzymes is maximal), and remains constant at 100-105% between 1 and 100 mM L-leucine. By comparison with the common placental profile cc, which reaches a value of 50% inhibition at an L-leucine concentration of 7.3 mM, the vv profile shows an inhibition of 50% at about 0.12 mM, or a 60 times lower concentration of L-leucine. This difference in the concentration of L-leucine which inhibits 50% is a convenient reference value for comparison of the common cc and variant vv inhibitions. Similarly, the difference between the inhibition of the heterozygous variant and common placental enzymes at the L-leucine concentration at which this difference is maximal (that is, 0.5-2.0 mM L-leucine) can also be regarded as a basis for comparison of the variant enzymes of placentae and cancer patients. Such a comparison is made in Table 1—reference cancer fluid and nine placental enzymes found.

Since the cancer patient enzyme was inhibited to the same extent as the heterozygote placental variants in 0.5 mM L-leucine, the leucine-sensitive Nagao isoenzyme in the sera and the fluid of cancer patients can be assumed to reflect the expression of both common and variant genes, and therefore to be a heterozygote. A similar degree of L-leucine inhibition has been reported for the Nagao isoenzyme<sup>2</sup> and for the electrophoretically fast-moving hepatoma-specific alkaline phosphatase<sup>4,5</sup>.

In connection with the greater L-leucine sensitivity of the variant, note that the stereospecific inhibition of mammalian alkaline phosphatase by L-amino acids<sup>13,14</sup> is not reported for any prokaryotic alkaline phosphatases. The variant enzyme described in this work should enable a more detailed study of this mode of inhibition; much

Table 1 Inhibition of extracts of nine variant placentae by 0.5 mM L-leucine, using 0.5 mM D-leucine as control compared with cancer ascites fluid

	% Inhibition (±s.d.)
Cancer ascites fluid	46.2±0.8
Variant 1	45.8±1.6
Variant 2	45.6±1.0
Variant 3	43.5±0.7
Variant 4	46.2±0.7
Variant 5	48.6±1.6
Variant 6	47.0±1.0
Variant 7	44.5±1.3
Variant 8	48.8±1.0
Variant 9	48.7±1.2

Assays were run in pentuplicate. Cancer ascites fluid provided by Dr L. L. Stolbach contained exclusively the variant enzyme (Nagao).

as the availability of mutant forms of bacterial enzymes, which are less feedback-inhibited by amino acids, has facilitated the study of feedback inhibition<sup>15</sup>.

The relationship of the variant enzyme to cancer is implicit in the similarity of the leucine sensitivity of the cancer patient enzyme with that of the placental variant, and in the similarity in immunoreactivity of this enzyme<sup>8</sup>. These two observations alone could not, however, be regarded as proof that the two enzymes represent the same genomic origin, or that the enzyme may mask a predisposition to certain cancers. Detailed structural and kinetic studies are being carried out to determine whether the variant and ascites enzymes are in fact identical in all respects. Additionally, epidemiological studies on the occurrence of various types of cancer in the families of children bearing the variant enzyme gene will be necessary.

## Late acquisition of a germ line antibody specificity

THE humoral immune response to most antigenic determinants is characterised by a highly heterogeneous population of antibody molecules derived from a large array of precursor cell clonotypes<sup>1-3</sup>. The response to certain antigenic determinants, however, is relatively restricted and may be dominated by a single homogeneous antibody species. In inbred strains of mice, such dominant antibody specificities are present in all individuals of a strain<sup>4-9</sup>, are characterised by identical idiotype determinants<sup>4-8</sup>, and are linked to heavy chain allotype markers<sup>7-10</sup>. Thus, these clonotypes are presumed to be a direct reflection of genetic information present in the germ line. A good example of an antibody specificity considered to be 'germ line' is the major clonotype responsive to phosphorylcholine in BALB/c mice, which is identical in its combining region to the TEPC 15 and S107 plasmacytoma proteins<sup>4-5</sup>. Representatives of the cell clone producing this phosphorylcholine-specific antibody have been found in high frequency (19±6 per 10<sup>6</sup> bone marrow-derived antibody-forming cell precursors (B cells)) in both conventionally reared and germ-free BALB/c mice<sup>11</sup>.

'Germ line' specificities can be enumerated by analysing the specificity repertoire of neonatal mice<sup>3,12,13</sup>. Since few

B cells are present during the first few days after birth, the neonatal repertoire may be thought to be quite restricted. Examination of the available clonotypes specific for the haptens dinitrophenol (DNP) and trinitrophenol (TNP) immediately after parturition revealed at least six clonotypes, three specific for DNP and three for TNP, present repeatedly in different individuals<sup>13</sup>. These predominant clonotypes can be represented by many (>100) cells. Other clonotypes specific for DNP or TNP occur only sporadically in the early neonatal B-cell population. By the seventh day after birth, however, such sporadic clonotypes represent most of the precursor pool, and presumably represent clonotypes expressed later in development than the early predominant ones<sup>13</sup>. It is conceivable that the all or none nature of the neonatal response to antigens like fluorescein<sup>3,13</sup> and the temporal hierarchy observed in the appearance of foetal and neonatal responses<sup>14,15</sup> may be accounted for by sporadic or late occurring clonotypes.

Since precursor cells representing the early predominant clonotypes occur with great regularity among individuals, and are present in large numbers at birth, they presumably were initiated early in foetal life and thus may be close reflections of the germ line genetic information for antibody specificity<sup>13</sup>. It should be interesting, therefore, to ascertain whether the dominant clonotypes observed in adult responses, for example, the TEPC 15 clonotype specific for phosphorylcholine, are expressed as neonatal predominant clonotypes, and thus fulfil another criterion for 'germ line' representation. In this report, the frequency of phosphorylcholine-specific B cells is quantitated in neonatal BALB/c mice. The results indicate that phosphorylcholine-specific clonal precursor cells, even those of the dominant TEPC 15 clonotype, appear quite late in neonatal development.

Spleen cells from BALB/c mice at various ages from birth to adulthood were transferred intravenously to lethally irradiated (1,300-1,600 r.) adult BALB/c mice immunised 2-3 months previously with 0.1 mg of *Limulus polyphemus* haemocyanin (Hy)<sup>2</sup>. Sixteen hours after transfer, spleen fragment cultures were prepared from recipients as before<sup>2</sup>, and cultures were stimulated *in vitro* for 3-4 d with either 1×10<sup>6</sup> M DNP-Hy or 5×10<sup>7</sup> M 3-(p-azo-phenylphosphorylcholine) - N - acetyl - L - tyrosylglycylglycine - haemocyanin (PPC-TGG-Hy), an antigen shown to maximise carrier recognition in anti-phosphorylcholine responses<sup>6</sup>. Culture fluids collected from day 9 to day 13 after culture initiation were analysed for the anti-phosphorylcholine or anti-DNP antibody by a sensitive radioimmunoassay. The binding of antibody to the antigen coupled to bromoacetyl cellulose immunoabsorbent was detected with <sup>125</sup>I-labelled rabbit anti-mouse Fab antibody<sup>2,6</sup>. Previous studies have demonstrated the donor origin of the antibody-producing cells<sup>16</sup>, the monoclonal nature of the antibody obtained<sup>2,12,16</sup>, the efficiency of detecting clonal precursors in this system (3.9%) (ref. 16 and unpublished results of A. Pickard and N.R.K.), and the efficiency of such stimulation for the analysis of neonatal B cells<sup>3,12,13,16</sup>. Antibody with the TEPC 15 idiotype was detected in an inhibition solid-

Table 1 Number of phosphorylcholine-specific foci and percentage of those foci positive for the TEPC 15 idiotype at various ages

Age (d)	Total No. of neonates	Total No. of cells analysed	No. of foci	% Foci with TEPC 15 idiotype
0-2	53	148 × 10 <sup>6</sup>	0	—
3-5	15	66 × 10 <sup>6</sup>	0	—
6-7	34	628 × 10 <sup>6</sup>	26	66
8-9	22	320 × 10 <sup>6</sup>	13	77
14	26	823 × 10 <sup>6</sup>	56	72
21	6	231 × 10 <sup>6</sup>	24	57
28	3	199 × 10 <sup>6</sup>	25	72

**Fig. 1** The frequency of clonal precursor cells specific for phosphorylcholine or DNP at various ages. Two to  $25 \times 10^6$  donor spleen cells from conventionally reared mice were transferred into an individual recipient, and the recipient spleen fragments were stimulated with PPC-TGG-Hy or DNP-Hy. Each small circle represents the phosphorylcholine-specific precursor cell frequency derived from one to ten donor spleens injected into two to eight Hy-primed recipients, the bars indicate the average frequency at each age. The adult precursor cell frequency for phosphorylcholine is derived from data published before<sup>11</sup>. Since no phosphorylcholine-specific foci were detected in 2- and 4-d-old donors, the bars at those ages denote the maximum precursor frequency if one focus had been detected. The open circles represent the average DNP-specific precursor cell frequency at various ages; the data have been published for neonates<sup>13</sup> and adults<sup>2, 10</sup>. The closed boxes indicate the average frequency and standard deviation of single DNP-specific predominant clonotypes, assuming that each of the three predominant clonotypes is represented equally in the early neonatal period. All the data are represented as the frequency of clonal precursor cells in  $10^6$  spleen cells, using a cloning efficiency of 3.9% as the correction factor<sup>10</sup>.

phase radioimmunoassay using anti-TEPC 15 sera raised in A/He mice<sup>6</sup>.

Table 1 shows that of the 53 neonates examined from birth to 2 d of age and the 15 neonates analysed from 3 to 5 d of age, no foci producing anti-phosphorylcholine antibody were detected. The first phosphorylcholine-specific clonotypes arise approximately 1 week after birth, and most of these clones are of the TEPC 15 idotype, as is the case in the BALB/c adult<sup>6</sup>. Figure 1 plots the frequency of DNP and phosphorylcholine-specific precursor cells in adults and neonates during the first several weeks of life. As reported previously, DNP-specific cells are present in high frequency at birth and remain relatively constant into adulthood<sup>12</sup>. Conversely, phosphorylcholine-specific precursor cells do not appear at all until day 6–7 after birth and remain in relatively low frequency for several weeks. Although, as Fig. 1 demonstrates, both conventionally reared neonates and adults show wide variations in phosphorylcholine-specific precursor frequency, the average neonatal frequency at 1 week old is eight times lower than the average adult precursor cell frequency.

The DNP-specific precursors present in the spleen during the first 5–6 d after birth are largely representative of only three predominant clonotypes<sup>13</sup>. A DNP-specific B cell represents one of 3,000 total B cells, therefore, the frequency of any one of the predominant clonotypes is one in

$10^4$  B cells. This is the same frequency observed for the three TNP-specific predominant clonotypes, which have been shown to be distinct from those specific for DNP by isoelectric focusing<sup>13</sup>. Thus while the frequency of each of the six known neonatal predominant clonotypes is one in  $10^4$  B cells, the data presented here indicate that early in development the TEPC 15 clonotype is 100 times less frequent than clonotypes presumably representing the earliest expression of the germ line genetic information for antibody specificities.

An analysis of 26 germ-free adults from various sources shows a frequency similar to conventionally reared adults, so that it is unlikely that antigen contact plays a significant role in either the generation of precursors with the TEPC 15 idotype or the maintenance in high numbers in adult mice<sup>11</sup>. Preliminary studies using germ-free neonates 5 and 8 d old demonstrate that the kinetics of appearance of phosphorylcholine-specific precursors in germ-free neonates is, in general, similar to that seen in conventionally reared mice (our unpublished results). Although neither maternal influences nor the presence of antigen can be ruled out specifically as the reason for the late acquisition of the TEPC 15 clonotypes during the neonatal period, the preliminary data with the germ-free neonates suggests that this is not the case.

Since the TEPC 15 clonotype is a prototype of a 'germ line' specificity, its late appearance during ontogeny may have significant implications for the mechanism by which the B-cell repertoire is acquired. This report and others have shown that the generation of the repertoire seems to be antigen independent<sup>3, 12, 13, 16</sup>, and the findings reported here indicate that the expression of even ubiquitous clonotypes may be relatively late events in neonatal development.

## Classical pathway activation of complement system by IgA anti-C3 antibody

ANTIBODIES which react with native C3 are present in high titre in adult<sup>1</sup> and neonatal saliva<sup>2</sup>. Although they belong to the IgA class they are macromolecules with a sedimentation coefficient of greater than 19S. They are also unusual in that their binding to C3 is dependent on the presence of

Table 1 C3 conversion induced by neonatal anti-C3 antibody

	EDTA plasma (%)	EGTA plasma (%)	Serum (%)	C2 Deficient serum (%)
IgG (50 µg)	< 5	< 5	38	5
Zymozan	< 5	31	36	23

Anti-C3 1:10			27	7
Anti-C3 1:20			17	< 5

calcium ions and they can be dissociated from C3 by 0.01 M EDTA<sup>1,2</sup>. Our preliminary studies on the properties of this antibody had shown that it could activate the complement system and in this paper we report investigations to determine whether this proceeds by way of the classical or alternative pathway.

Activation of the complement system was assessed by measuring the conversion of C3 occurring in normal human serum after adding anti-C3 antibody, the amount of conversion being calculated by planimetry<sup>3</sup>. Dilutions of purified antibody<sup>2</sup> were added to equal volumes of fresh human serum, EDTA plasma, EGTA plasma and C2-deficient human serum, and then incubated at 37 °C for 45 min. Heat-aggregated IgG and zymozan were included as positive controls. The results obtained are summarised in Table 1. Both the aggregated IgG and the zymozan produced C3 conversion in normal serum. The aggregated IgG did not convert C3 in EGTA plasma or C2 deficient human serum whereas zymozan produced C3 conversion in both sera. Conversion of C3 occurred when purified anti-C3 antibody was added to human serum and the amount of conversion was proportional to the amount of antibody added. No conversion of C3 occurred when antibody was added to C2-deficient human serum or EGTA plasma. C3 conversion in normal guinea pig serum and C4-deficient guinea pig serum was assessed qualitatively after immunoelectrophoresis in 1% agar, diluted in barbitone buffer pH 8.6 containing 0.01 M EDTA. The antibody, although capable of converting C3 in normal guinea pig serum, failed to convert C3 in C4 deficient serum (Fig. 1).

The ability of the antibody to activate C1 directly was

Fig. 1 Results of immunoelectrophoresis showing conversion of C3 in normal guinea pig serum (GPS) but no conversion in C4 deficient guinea pig serum (C4D). a, C4D and zymozan; b, C4D and anti-C3 antibody; c, GPS and anti-C3 antibody; d, GPS, EDTA to 0.01 M and anti-C3 antibody. Trough contains goat anti guinea pig C3 (Nordic Diagnostics).

then examined in serum from a patient with hereditary angioneurotic oedema which contained only 10% of the normal concentration of C1 inhibitor. Anti-C3 antibody (100 µl) was added to 800 µl of complement buffer, 100 µl of serum and 50 µl of 1 M acetyl tyrosine ethyl ester and then incubated with constant stirring at 37 °C. C1 was measured enzymatically by the hydrolysis of the ester<sup>4</sup>. When antibody was excluded from the mixture very little spontaneous activation of C1 took place, but the addition of purified antibody or heat aggregated IgG resulted in rapid activation of C1.

The observations that anti-C3 antibody in combination with antigen can activate C1 directly and that it fails to convert C3 in C2 and C4 deficient serum indicates that complement activation requires the early components C1, C4 and C2. In man, previous reports have shown that complexes or aggregates of IgA activate the complement system via the alternative pathway<sup>5</sup>. Our studies on the salivary anti-C3 antibodies show for the first time that IgA antibody can also activate the complement system via the classical pathway. This pattern of activation may account for the observations that the haemolytic titres of C3 and C4 are low and that inactivated forms of these two proteins are present in colostrum<sup>6</sup>, this secretion being another source of the anti-C3 antibody in humans<sup>7</sup>. Since these antibodies are macromolecular in size and have a number of unusual properties our findings may not be applicable to other IgA antibodies.

We thank Dr D. K. Peters for the C2 deficient serum and Professor P. J. Lachmann for helpful discussion.

## Antibodies against homogeneous epoxide hydratase provide evidence for a single enzyme hydrating styrene oxide and benz(a)pyrene 4,5-oxide

THE microsomal enzyme epoxide hydratase (EC 4.2.1.63) is potentially important in the inactivation of metabolically produced epoxides which may be responsible for the mutagenic and/or carcinogenic properties of polycyclic hydrocarbons (for reviews see refs 1-3). Reports<sup>4,5</sup> suggest that the enzyme plays a dual role in (a) producing proximate carcinogens which, after biotransformation to carcinogens by microsomal mono-oxygenase(s) are (b) inactivated by epoxide hydratase. As this enzyme can be induced<sup>6-8</sup>, activated<sup>9-10</sup> and inhibited<sup>9-13</sup> it should be useful in studies of the mechanism of chemical carcinogenesis: some inverse correlations have been reported between susceptibility to carcinogenesis by polycyclic hydrocarbons and inducibility of epoxide hydratase at different stages of development in the rat<sup>14</sup>. Most investigations of this enzyme<sup>6-10,15-18</sup>, however, have involved radiometric assay with <sup>3</sup>H-styrene oxide as substrate<sup>18</sup>. There is evidence that the enzyme(s) responsible for the hydration of this substrate are also involved in hydration of epoxides, derived

from polycyclic hydrocarbons<sup>9,18</sup>, while other evidence suggests the presence of several epoxide hydrolases in the microsomal membrane<sup>7,9,10,19</sup>. Thus it was not known whether information about epoxide hydrolase obtained with styrene oxide as substrate applied to the enzyme(s) responsible for hydration of epoxides derived from polycyclic hydrocarbons. Using antibodies raised against a homogeneous epoxide hydrolase preparation and other criteria described here, we have now found evidence that intact microsomal membranes contain a single enzyme able to hydrate styrene oxide and benz(a)pyrene, 4,5-oxide, a K-region epoxide.

Epoxide hydrolase was solubilised from adult male Sprague-Dawley rat liver microsomes and purified to homogeneity as established by gel electrophoresis, analytical ultracentrifugal and immunological criteria<sup>20</sup>. Antibodies to this preparation were raised in New Zealand white rabbits. The animals were immunised intradermally at several sites along the flank with 100 µg of pure epoxide hydrolase in Freund's complete adjuvant. Booster injections of 50 µg of protein in 50 mM Na phosphate buffer were given intradermally 8 and 16 weeks later. Rabbits were bled and serum was collected 8–10 d after the last injections. A 200 µl sample of either crude epoxide hydrolase solution (solubilised microsomes, 1.4 mg protein) or homogeneous epoxide hydrolase (46 µg) was kept for 18 h at 0–4 °C in the presence of a constant amount (200 µl) of serum containing various amounts of antiserum. Controls were kept in the same conditions but in the presence of control serum. Precipitated antigen-antibody complexes were sedimented by centrifugation at 8,000g for 20 min and supernatant fractions were assayed for epoxide hydrolase activity in the absence of Tween 80 with substrates styrene oxide<sup>10</sup> and benz(a)pyrene 4,5-oxide (H. U. Schmassmann *et al.*, unpublished). To determine the inhibitory potency of the antibodies, enzyme preparations were kept in the presence of antiserum for 15 min at room temperature and then assayed without previous centrifugation. In the experiments with low molecular weight inhibitors, these were added to the incubation mixture at zero time with no preincubation, in 10 µl of acetonitrile with styrene oxide and in 25 µl of acetonitrile with benz(a)pyrene 4,5-oxide as substrates, while controls had the same amounts of acetonitrile.

Figure 1 shows the results of an immunoprecipitation

**Fig. 1** Immunoprecipitation of epoxide hydrolase activity with styrene oxide (▲) and benz(a)pyrene 4,5-oxide (○) as substrate in crude hydrolase solution (solubilised microsomes) (a), and homogeneous hydrolase (b) by antibodies raised against an epoxide hydrolase preparation homogeneous by gel electrophoresis, analytical ultracentrifugal and immunological criteria. The results are expressed as percentage of the activity of samples treated similarly with serum from control animals. These control activities were 10.6 and 432 nmol styrene glycol and 3.7 and 136 nmol benz(a)pyrene 4,5-dihydrodiol per min per mg protein with the crude hydrolase solution and the homogeneous hydrolase, respectively. Differences between these controls and samples without serum protein were always less than 30% and were noticed only when homogeneous epoxide hydrolase was used, probably because the protein content present in those assay mixtures was extremely low in the absence of serum proteins.

**Fig. 2** Inhibition of epoxide hydrolase activity with 2 mM styrene oxide (a) and 0.15 mM benz(a)pyrene 4,5-oxide (b) as substrate by 2 mM 1,1,1-trichloropropene 2,3-oxide (■), 2 mM cyclohexene oxide (▨) and 2 mM *trans*-stilbene oxide (□). Enzyme preparations were: 1, rat liver microsomes; 2, solubilised microsomes; 3, phosphocellulose column effluent; 4, homogeneous epoxide hydrolase. The specific activities of the various preparations reflecting their relative purification were: 1, 5.01; 2, 8.91; 3, 260; 4, 600 nmol styrene glycol per min per mg protein. Inhibitors were added at zero time in acetonitrile solution. Controls received the same amount of acetonitrile. Results are expressed as percentage inhibition compared with such controls. ns, not significant (level of significance:  $P < 0.05$ ).

experiment. Antibodies raised against homogeneous epoxide hydrolase, which had been purified<sup>20</sup> using an assay with styrene oxide as substrate<sup>10</sup>, precipitated epoxide hydrolase activity towards both styrene oxide and benz(a)pyrene 4,5-oxide. Precipitation, which was dose-dependent, occurred when antiserum was incubated with either the pure enzyme or the crudest soluble preparation (solubilised microsomes). Immunoprecipitation was complete at the higher concentrations of antiserum. This suggested the presence of a single enzyme responsible for the hydration of the two substrates. On the other hand, there may be several immunologically cross reactive epoxide hydrolases or some epoxide hydrolase species may be inactivated differentially but completely during solubilisation of the microsomes. But although the extent of inhibition of epoxide hydrolase activity by antiserum was different in microsomes (20–30%) compared with soluble preparations (70–80%), inhibition of the hydration of the two substrates was always similar ( $\pm$  less than 10% of the mean) (data not shown). Furthermore, the relative potency of low molecular weight epoxide hydrolase inhibitors remained essentially the same throughout purification. This was true for either substrate. As Fig. 2 shows, when styrene oxide was used as substrate the membrane-bound enzyme (1), the crudest solubilised preparation (2), a partially purified preparation (3), and homogeneous epoxide hydrolase (4), were all inhibited completely by 1,1,1-trichloropropene 2,3-oxide, very strongly ( $\sim$  60–80%) by cyclohexene oxide and not significantly ( $< 10\%$ ) by *trans*-stilbene oxide. Epoxide hydrolase activity with benz(a)pyrene 4,5-oxide as substrate was also inhibited by these agents to very similar extents in the different enzyme preparations. Finally, only a single side fraction during purification had detectable epoxide hydrolase activity towards either of the substrates used. The ratio of the specific activities towards the two substrates was the same in this single side fraction as in the fraction containing the bulk of epoxide hydrolase activity.

These results, taken together, strongly suggest that a single enzyme is involved in the hydration of both styrene oxide and benz(a)pyrene 4,5-oxide in rat liver microsomes. Thus, information already acquired about epoxide hydrolase, using styrene oxide as substrate, seems to be directly relevant to the enzymatic entity responsible for hydration of benz(a)pyrene 4,5-oxide, a K-region epoxide and, most probably, many epoxides derived from several carcinogenic polycyclic hydrocarbons.

## Complexity of germline and somatic DNA in *Ascaris*

DURING the early determination of the blastomeres in the nematode *Ascaris* chromosomal segments are eliminated in the pre-somatic cells (chromatin diminution). In the germline, however, all the chromatin is preserved. Similar genome differentiation phenomena have been published<sup>1–3</sup>. Since no molecular description of chromatin diminution has been made we have begun to study the chromosomes in germline and somatic cells<sup>4</sup>. It was found that the amount of DNA occurring only in the germline chromosomes is not constant<sup>5</sup> and that this DNA is not enriched in rDNA<sup>6</sup>. There is no evidence that the germline-limited DNA is transcribed *in vivo*<sup>7</sup>. The results presented here show that the germline DNA of *Ascaris* contains highly repetitive components, eliminated by the diminution process. Their possible molecular function in connection with germline-soma differentiation and chromosomal behaviour is discussed.

By means of Feulgen photometric measurements and Burton's reaction, we determined the DNA content of germline and soma genomes of *Parascaris equorum* race *univalens* as 1.2–2.1 pg and 0.25 pg, and *Ascaris lumbricoides* var. *suis* as 0.32 pg and 0.25 pg, respectively. Therefore, *Parascaris* contains up to 85% germline-limited DNA but *A. suis* only 22%. An analysis of melting curves had shown that the G+C content of the germline DNA differs from that of soma DNA<sup>8</sup>. Buoyant density profiles of DNA in neutral CsCl gradients demonstrate the presence of germline satellites in both species (Fig. 1). Germline DNA of *P. equorum* contains two satellites of sizes unique in the animal kingdom, with densities 1.697 g cm<sup>-3</sup> and 1.692 g cm<sup>-3</sup> (Fig. 1a); the dense shoulder at 1.700 g cm<sup>-3</sup> represents the single copy DNA. After denaturation and reassociation to low *C<sub>0</sub>t* (Fig. 1a') the highly repetitive components (satellites) form one peak at 1.703 g cm<sup>-3</sup>, making up about 85% of the total germ-

Fig. 1 Buoyant density pattern of *Ascaris* DNA centrifuged in neutral CsCl. Left column, native DNA; right column, denatured unsheared DNA reassociated to *C<sub>0</sub>t* 0.5 mol nucleotide s<sup>-1</sup>. a, a', Spermatid germline DNA of *Parascaris equorum* race *univalens*; b, b', spermatid germline DNA of *Ascaris lumbricoides* var. *suis*; c, c', larval soma DNA of *P. equorum*; d, d', larval soma DNA of *A. suis*. Marker DNA was from *Micrococcus lysodeikticus* with density taken as 1.731 g cm<sup>-3</sup>, implying an *E. coli* DNA density of 1.710 g cm<sup>-3</sup> in our analytical centrifugations. Mitochondrial DNA of *Ascaris* bands at 1.686 g cm<sup>-3</sup> (ref. 11). For further explanation see text.

line DNA. The single copy DNA, still denatured, forms the side peak at 1.715 g cm<sup>-3</sup>. The sharp profile of the reassociated fraction may indicate short basic nucleotide sequences of the satellite DNA. Since only one peak is generated one might deduce that there is a sequence relationship between the two satellites. In *A. suis* the satellite DNA at 1.697 g cm<sup>-3</sup> (Fig. 1b) is not sharply separated from the main band DNA as reported earlier<sup>9</sup>. After denaturation and reassociation to low *C<sub>0</sub>t*, however, the single-stranded DNA has shifted away from the reassociated satellite DNA (Fig. 1b'), which is considered to be about 23% of the germline DNA. In the native larval somatic DNA of both species (Fig. 1c and d) satellites are absent. Apparently they have been lost during chromatin diminution. Even after density transposition of single copy DNA by denaturation and following low *C<sub>0</sub>t* reassociation there is no evidence for satellite DNA (Fig. 1c' and d'). If we incubate denatured unsheared soma DNA of *A. suis* to low *C<sub>0</sub>t* and subsequently digest it by single-strand specific endonuclease, 4% is revealed as enzyme resistant on CsCl centrifugation.

Reassociation kinetics (Fig. 2) of total genome DNA of *A. suis* demonstrate that 17.5% of testis DNA (predominantly germline DNA) consists of repeated sequences whereas the larval soma DNA does not contain any measurable highly repetitive component. This latter finding contradicts the data of Tobler *et al.*<sup>10</sup> who reported a value of 10% repetitive DNA

for soma DNA. In spermatid DNA which is not contaminated by follicle epithelium DNA and contains only insignificant amounts of mitochondrial DNA repetitive sequences make up 20–22% (refs 8 and 10).

The slowly-reassociating DNA of germline and of soma reassociates homogeneously with second order kinetics (Fig. 2), and the reassociation rate constants correspond well. This indicates that there is identical single copy DNA complexity in the germline and the soma. The  $C_0t_{1/2}$  values corrected for 50% G+C (ref. 11) suggest that the somatic DNA as well as the plurivalent germline chromosomes constitute the unit genome<sup>12</sup> since their analytical values compare well with the reassoci-

**Fig. 2** Reassociation kinetics, analysed optically, of larval soma DNA (■), of total testis (germline) DNA (●) and single copy testis DNA (○) of *A. suis*, of *E. coli* DNA (▼) as a standard and of single copy DNA of *Gallus domesticus* (△). Larval DNA was extracted from embryos, testis DNA from whole gonads. The DNA isolation involved proteinase K (Merck) digestion of the lysates, deproteinisation by phenol, pancreatic RNase and T<sub>1</sub> RNase digestion; and hydroxyapatite column chromatography. DNA was sonicated in 0.01 M Tris-HCl pH 7.1 to a mean fragment size of 400 nucleotide pairs. Reassociation buffer was 0.01 M Tris-HCl, 2 M NaClO<sub>4</sub> pH 7.1. After melting of the DNA in a water-jacketed cuvette (pathlength 1 mm) the temperature was lowered within seconds to incubation temperature (25 °C beneath  $T_m$ ). The absorbance was recorded by means of a double beam equipment. Timed absorbance values were stored with an interface in a computer. For the description of the second order reaction the following equation was taken

$$(\Delta_t^{\text{ren}})^{-1} = (\Delta_0^{\text{ren}})^{-1} + kt$$

$$\text{with } \Delta_t^{\text{ren}} = A_t - A_{\infty}^{\text{ren}} \\ \Delta_0^{\text{ren}} = A_0 - A_{\infty}^{\text{ren}} \\ k = (\Delta_0^{\text{ren}} \times t_{1/2})^{-1}$$

$A_t$  is the absorbance at time  $t$ ,  $A_0^{\text{ren}}$  that after deducting collapse hypochromicity<sup>13</sup>,  $A_{\infty}^{\text{ren}}$  that for infinite reaction, which is approximated by linear regression for the time interval within which 75% of the single copy DNA has reassociated. From the regression line the  $C_0t$  curves were obtained using:

$$\Delta_t^{\text{ren}} \times (\Delta_0^{\text{ren}})^{-1}$$

as fraction of denatured DNA.  $C_0t$  was transformed to  $Ec_0t$  (ref. 16) (incubation buffer 0.12 M phosphate). In 2 M NaClO<sub>4</sub> reassociation is 5.5 times faster than in 0.12 M phosphate. The dashed lines are theoretical second order curves. For *E. coli* DNA  $Ec_0t_{1/2} = 4.8$ . The germline DNA from testis contains 17.5% fast reassociating sequences. The  $C_0t$  curve of germline single copy DNA ( $Ec_0t_{1/2} = 410$ ) was evaluated from the curve of total testis DNA. For larval soma DNA  $Ec_0t_{1/2} = 440$ . For single copy chicken DNA  $Ec_0t_{1/2} = 1,190$ . DNA concentrations were 461  $\mu\text{g ml}^{-1}$  for *E. coli*, 772  $\mu\text{g ml}^{-1}$  for *Ascaris* testis, 1,172  $\mu\text{g ml}^{-1}$  for *Ascaris* larva, and 862  $\mu\text{g ml}^{-1}$  for *Gallus*.

**Table 1** Comparison of genome sizes and kinetic complexity in daltons

DNA (% G+C)*	Analytical value	Kinetic value†
<i>E. coli</i> (50)	$2.7 \times 10^9$	
<i>A. suis</i> soma (40.8)	$1.5 \times 10^{11}$	$1.9 \times 10^{11}$
<i>A. suis</i> germline (40.8)	$1.9 \times 10^{11}$	$2.2 \times 10^{11}$
<i>Gallus domesticus</i> (42)	$7.5 \times 10^{11} \ddagger$	$5.9 \times 10^{11}$

\*G+C content of single copy DNA.

‡Ref. 13.

ation kinetic values using *Escherichia coli* DNA as a standard, within the limitations of the method (Table 1). Consequently, in the germline genome there is no room for any appreciable amount of germline-limited single copy DNA (estimated to be one half of germline-limited DNA by ref. 10), which could be detectable by means of reassociation kinetics studies. This is independently confirmed by the agreement of the two percentages; the germline-limited DNA (22%) and the fast-reassociating DNA fraction (20–22%) of the spermatid (that is, germline) genome. If one considers both the cytology of diminution and that the soma DNA does not contain satellite DNA then the identity of those two percentages shows that the reiterated sequences are clustered.

We have repeatedly measured the reassociation of the more complex single copy DNA of *Gallus domesticus*. Using *E. coli* DNA as a standard, the  $C_0t_{1/2}$  value was always estimated to be

**Fig. 3** Reassociation, measured by hypochromicity, of isolated highly repetitive components of soma and germline DNA of *A. suis*. Sheared larval soma DNA and testis DNA were denatured and incubated to  $Ec_0t = 3$ . The reassociated DNA was bound on to a 60 °C hydroxyapatite column equilibrated in 0.12 M phosphate, the absorbed fraction eluted by 0.35 M phosphate washing. Soma DNA yields a bound fraction between 3.5–6.5%, testis DNA about 14%. Reassociation of fast reassociating sequences was done in 0.03 M phosphate, where reassociation is 75 times slower than in 0.12 M phosphate<sup>16</sup>. Reassociation was recorded in double beam using water-jacketed cuvettes (10 mm pathlength) and temperature measuring equipment in the reference cuvette. In the experiment shown, the soma DNA fraction (■), contaminated by single copy DNA, renatured to 55%, of which 35% (2.3% of total soma DNA) occurred within 30 s. For this fraction  $\Delta_0^{\text{ren}}$  was 0.16, hence at  $Ec_0t = 10^{-5}$  this fraction (foldback DNA) had completely renatured. The other reassociating fraction makes up 20% (1.3% of total soma DNA). The reassociation of the highly repetitive testis DNA (●) may be interpreted as the reaction of three components: one reassociating with  $t_{1/2} = 5.7$  min and  $\Delta_0^{\text{ren}} = 0.057$ , thus yielding an  $Ec_0t_{1/2}$  of  $2 \times 10^{-4}$ , making up some 70% of the fast reassociating sequences. The additional 30% ( $\Delta_0^{\text{ren}} = 0.024$ ) contain 13% (2.3% somatic foldback DNA correspond to 1.8% in the germline; 1.8%:14% foldback DNA and 17% highly repetitive sequences. For symbols see legend of Fig. 2. Abscissa: time of incubation; in s for soma DNA, in min for germline DNA.

smaller than expected from the analytical genome size for which divergent values have been published, however.

In order to characterise the repeated DNA sequences, they were isolated from total DNA. Reassociation to low  $C_0t$  of denatured sheared total larval soma DNA of *A. suis* (Fig. 3) yields a renatured fraction of approximately 4%. This was isolated as 0.35 M phosphate buffer fraction by HAP column chromatography using 0.12 M phosphate as the discriminating concentration between single and double-stranded fragments. The proportion of the fast-renaturing DNA is 2.3% of the total DNA. It has completely renatured at  $Ec_0t < 10^{-5}$ , and has a sharp melting profile. Its hyperchromicity, however, is low. Its broad banding profile in neutral CsCl reveals its network configuration; it is also highly resistant to endonuclease. These are all characteristics of foldback DNA<sup>14</sup>. Continued reassociation, after the foldback DNA has completely renatured, reveals a slowly reassociating component which is about 1% of the total DNA. Its percentage is small compared with that found in other organisms. If one accepts that intermediate repetitive sequences have a regulatory function<sup>15</sup>, the small amount present in *Ascaris* reflects the simple organisation of this organism.

From denatured sheared testis (that is, germline) DNA after reassociation to low  $C_0t$  the reassociated fraction isolated by HAP chromatography makes up 14% of the total DNA. Its reassociation indicates fast reassociating sequences in addition to the ubiquitous foldback DNA. Their reassociation curve (Fig. 3) may be interpreted as the reaction of three components: the foldback DNA and two highly repetitive classes of DNA: One makes up 21% of the germline-limited DNA which reassociates with  $C_0t_{1/2} < 10^{-4}$ , the other predominant one (79%) reassociates with  $C_0t_{1/2} = 2 \times 10^{-4}$ . Alternatively, the initial delay of the reaction, indicated by the continuous decline of the slope of the curve in Fig. 3, may be caused by increasing hyperpolymerisation<sup>16</sup> during the reassociation of only one component degenerated in its basic nucleotide sequence. In neutral CsCl, the isolated germline-limited DNA forms one sharp peak. This, together with its high hyperchromicity, indicates its highly native state after reassociation. Its  $T_m$  is 3 °C lower than that of the foldback DNA.

The observations on the abnormal cleavage of the *Ascaris* egg<sup>17</sup> have shown that the existence of germline limited chromatin is a sufficient criterion of the germline quality of a blastomere; the irradiation of germline blastomeres<sup>18</sup> showed that the existence of that chromatin is necessary. The data presented here demonstrate, for the first time for an organism with germline-limited chromatin, that the presence of highly repetitive DNA components in itself is sufficient for the genetic status of a germline cell. Yet, in spite of the developmental significance of this type of chromatin, the molecular function of its highly repetitive DNA components remains obscure.

But three properties of the *Ascaris* germline chromosomes may be related to this function. (1) The highly repetitive DNA sequences are components of the heterochromatic sections of the germline chromosomes. After diminution the chromosomes are euchromatic. Therefore, these sequences might possibly suppress the activity of somatic genes, as happens in position effect variegation, and thus be responsible for the maintenance of the germline quality. (2) Germline chromosomes have a tendency to form plurivalent chromosomes. In extreme cases, the entire genome is integrated into a single plurivalent chromosome. The tandem reiteration of distally localised sequences allows the formation of sticky ends and, consequently, the linking together of chromosomes. Aggregation of the minute somatic single chromosomes to large plurivalent chromosomes prevents mistakes in meiotic distribution. (3) The germline chromosomes are holocentric<sup>4</sup>. The germline-limited chromatin has kinetic activity in anaphase. This property, which is lost in preparation for diminution, increases the chromosome manoeuvrability. This latter must be guaranteed, especially in parasitic organisms such as *Ascaris* which produce exceedingly large quantities of gametes. These observations in *Ascaris* and

their interpretations support quite well Walker's ideas<sup>19</sup> on the significance of highly repeated sequences.

## No detectable satellite DNA in supernumerary chromosomes of the grasshopper *Myrmeleotettix*

SUPERNUMERARY (B) chromosomes and satellite (simple sequence) DNA are enigmatic chromosomal phenomena, in that both are variable additions to the main chromosome complement. It has been suggested that differences between, and constancy within, certain related species for satellite DNA, implies that it may play a role in speciation by a series of saltatory steps<sup>1-3</sup>. Similarly, B chromosomes may affect recombination<sup>4</sup> or rate of development<sup>5</sup>, or bring about diploidising effects in hybrids of closely related species<sup>6</sup>. There is still, however, no clear understanding of the functions of either of these variables.

The first report of between and within-population variation in satellite DNA, associated with the presence or absence of B chromosomes in the grasshopper *Myrmeleotettix maculatus*<sup>7,8</sup>, suggested that there might be a closer relationship between satellite DNA and supernumerary chromosomes. Analysis of sedimentation patterns of total DNA in neutral caesium chloride showed that the DNA of B chromosome-containing individuals, from several different populations, contained satellite DNA not found in individuals lacking B chromosomes. Furthermore, both main-band and satellite DNA were found to vary in buoyant density in populations from different localities.

Several studies, however, on the heterogeneity of B chromosome DNA in plants<sup>9-11</sup>, have failed to reveal large fractions of highly repetitive or moderately repetitive DNA exclusive to the B chromosomes. Detailed examination of several parameters of base composition of A and B chromosome DNAs were made in the wheat group of species<sup>11</sup>. These included profiles of thermal dissociation of homologous and heterologous duplexes, differential melting curves in strictly comparable den-

**Fig. 1** Analytical ultraviolet absorbance patterns, after sedimentation to equilibrium in neutral CsCl for 20 h at 44,000 r.p.m. at 25 °C on a Centriscan 75 analytical centrifuge. *a-f*, Pronase-digested lysates of testes or ovaries of single individuals. Tissue was lightly ground in glass homogenisers in 150  $\mu$ l of 0.5% sodium lauryl sulphate, 0.1 M EDTA, 0.05 M Tris, pH 8.4 and lysed for 2 h at room temperature. After lysis, 0.5 ml of 10 mM Tris-HCl, pH 7.8 and 100  $\mu$ l of self-digested Pronase (1 mg ml<sup>-1</sup>) were added and incubated for 2 h at 37 °C. Solid CsCl (ultra-centrifuge grade) was added to an initial density of 1.700 g cm<sup>-3</sup>. A sample of 2  $\mu$ l of marker DNA ( $A = 4$ ) of *Pseudomonas aeruginosa* (density = 1.726 g cm<sup>-3</sup>) was added. *g-h*, Bulk testes of 25 individuals were homogenised in 4 M CsCl (initial density = 1.4 g cm<sup>-3</sup>) in a glass homogeniser. The homogenate was centrifuged in a 8  $\times$  14 ml rotor of an MSE 65 centrifuge for 20 h at 40,000 r.p.m. at 25 °C. The pellet was dissolved in 4 ml of 1  $\times$  SSC (0.15 M NaCl + 0.015 M Na citrate) and incubated at 37 °C successively with  $\alpha$ -amylase (250  $\mu$ g ml<sup>-1</sup>) for 1–2 h, RNase (250  $\mu$ g ml<sup>-1</sup>, preheated to 80 °C for 5 min) for 1–2 h, and Pronase (1 mg ml<sup>-1</sup>, self-digested at 37 °C for 2 h) for 1–2 h. Insoluble material was removed with low speed centrifugation and the DNA was pelleted for 1–2 h at 40,000 r.p.m. at 4 °C and dissolved in 10 mM Tris-HCl, pH 7.8. Conditions for analytical ultracentrifugation were as in *a-f*. *a*, Southwold  $\delta$  (no B); *b*, Mildenhall  $\delta$  (no B); *c*, Mildenhall  $\delta$  (one B); *d*, Mildenhall  $\delta$  (two B); *e*, Foxhole  $\delta$  (no B); *f*, Foxhole  $\delta$  (one B); *g*, Mildenhall  $\delta$  (bulk extract) (no B); *h*, Mildenhall  $\delta$  (bulk extract) (one B).

aturation conditions and equilibrium sedimentation patterns in neutral CsCl and actinomycin D–CsCl gradients. Within the limits of resolution of these experiments, it has been shown that the B chromosomes contain representatives of the spectrum of repeated sequence families present on the A chromosomes: there are no discrete B chromosome fractions of DNA which form satellites, or which are not homologous to A chromosome DNA when they are hybridised together.

Although these studies demonstrate that the presence of distinct satellite DNA is not a general property of B chromosomes *per se*, the *Myrmeleotettix* satellite could well reflect the origin and composition of that particular B chromosome system. The large, varying amounts of satellite demonstrated in this grasshopper, however, were far greater than expected from the measured size of the B chromosome. The unusually large variations in main-band and satellite buoyant densities from different populations are also difficult to explain. As part of a general study of interpopulation differences of satellite DNA in Orthoptera and *Drosophila*, the anomalous situation in this grasshopper has been re-examined.

Male and female adult individuals of *Myrmeleotettix maculatus* were collected during August and September 1975 from wild East Anglian populations in the Mildenhall/Foxhole Warren area, where a 50% B chromosome frequency is found. Others were collected from a coastal population near Southwold, where no B chromosomes occur. Testes and ovaries were vivisected in cold isotonic saline and cleaned of fat body. Part of each testis or ovary was placed in acetic alcohol fixative before determination of the B chromosome status in propionic orcein squash preparations. The remainder was used fresh for DNA extraction or stored in a deep freeze until required. Females were injected with colcemid 1 h before dissection, to facilitate the analysis of ovariole mitoses.

DNA extracts were obtained both from single individuals and from the bulk extraction of the homogenised gonads of 25 individuals with, and 25 without, B chromosomes. Details of the two methods are given in the legend to Fig. 1. The methods of extraction were identical to those already published<sup>7,8</sup>, to ensure direct comparability of results. Pronase-treated lysates of individual gonads were loaded directly into analytical cells of an MSE Centriscan centrifuge, in neutral CsCl. The DNA of bulked gonads, after removal of protein, polysaccharide and RNA contaminants, was sedimented to equilibrium in neutral CsCl and actinomycin D–CsCl gradients. All gradients were scanned with Schlieren visible light optics to detect the presence of glycogen and other ultraviolet (254 nm) and visible light (540 nm) absorbing contaminants. If present, such extraneous ultraviolet-absorbing peaks have been removed from the traces for clarity.

A selected range of ultraviolet absorbance profiles of grasshopper DNA, after sedimentation to equilibrium in neutral CsCl, are shown in Fig. 1. No satellites to the main band were found in any of the grasshoppers with 0, 1 or 2 B chromosomes; of either sex, in any population sampled. The main-band buoyant densities and the overall mean buoyant density and standard error are given in Table 1. No significant differences were observed between genotypes or between populations.

Profiles of grasshopper DNA after sedimentation to equilibrium in actinomycin D–CsCl gradients showed a skewed spread of main-band DNA, indicating considerable heterogeneity in base composition (Fig. 2), causing differential binding of the antibiotic to fractions of varying GC content. No main-band cryptic satellites nor changes in main-band skew or spread were revealed in such gradients in the presence of B-chromosome DNA. It is interesting that direct loading and analytical centrifugation of comparable lysates of individual testes,

females throws some doubt on the reported B chromosome-satellite DNA correlation in this species. The present results suggest considerable similarity in base composition of A and B chromosome DNA, as found in several plant species<sup>9-11</sup>.

It is difficult to explain the presence of satellite DNA and the variation in satellite and main-band base composition previously reported. An exclusion of B-chromosome responsibility for the presence of the satellite leaves the possibilities of either an unrelated form of intra-population variation for satellite, or a pathogen or glyco-gen contamination.

We thank Godfrey Hewitt, Ian Gibson and Richard Flavell for discussion, and David Webb for technical assistance.

## Mechanism of differential Giemsa method for sister chromatids

THE 33258 Hoechst fluorescence<sup>1</sup> and 33258 Hoechst-Giemsa<sup>2</sup> methods for differential staining of bromodeoxyuridine (BrdU)-incorporated chromatids are attractive because of their rapidity and high sensitivity in revealing small sister chromatid exchanges which escape detection by autoradiography. Since carcinogen-induced chromatid breaks are associated with sister chromatid exchanges<sup>3</sup> and breakage formation parallels carcinogenesis in typical cases<sup>4,5</sup>, these methods are essential for understanding the role of chromosome aberrations in carcinogenesis. We show here that other photosensitive dyes such as thionin can replace 33258 Hoechst in the latter method and that the mechanisms of the differential Giemsa method involves photolysis of the BrdU-substituted DNA combined with these photosensitive dyes.

Fresh bone marrow cells from Long-Evans rats were cultured for two rounds of cell cycle or 26 h in thymidine-free F12 medium containing 10% foetal calf serum and 2 µg ml<sup>-1</sup> BrdU. Colchicine was added 2 h before collection. Cells were collected, treated with 0.075 M KCl, fixed in 1:3 acetic methanol, spread and air dried on glass slides. Our basic procedure consisted of 33258 Hoechst treatment, exposure to light and Giemsa staining. In addition to 33258 Hoechst, various metachromatic dyes such as thionin, toluidine blue, methylene blue, and neutral red were used successfully. They were dissolved in distilled water at a concentration of 10<sup>-3</sup>-10<sup>-8</sup> M. Chromosome specimens were dipped in distilled water, treated with the above dye solutions for 10 min, rinsed in water, mounted with 0.16 M sodium phosphate and 0.04 M sodium citrate (pH 7.0)<sup>1</sup>, and exposed to strong sunlight (noon, clear summer days) for 5 min-3 h. Thereafter, the coverslips were removed and

the cells were stained for 15 min in 2% Giemsa (Merck) solution in 0.05 M phosphate buffer (pH 6.8). Table 1 indicates that differential chromatid staining depends on the amount of 33258 Hoechst bound and the exposure to light. For routine staining,  $10^{-4}$  M 33258 Hoechst (5 mg per 100 ml) with exposure to sunlight for 15–30 min or  $10^{-3}$  M

**Table 1** Influence of 33258 Hoechst and period of exposure to sunlight on differential Giemsa staining of sister chromatids

$10^{-8}$	—	—	—	—	—	±	+

++, Excellent differentiation; +, moderate; ±, trace; —, negative

thionin (23 mg per 100 ml) with exposure time of 2 h gave an excellent differential staining (Fig. 1a). A longer exposure time was necessary with other dyes. Heating in  $2\times$ SSC or in water at  $60^{\circ}\text{C}$  for 2 h (ref. 2) was not essential because differential staining was obtained in the specimens maintained at  $20\pm 2^{\circ}\text{C}$  during the whole course of the staining procedure.

Latt suggested that the fluorescence of 33258 Hoechst

**Fig. 1** Metaphase bone marrow cell grown for 26 h in BrdU-containing medium. ( $\times 3,300$ ). a, Sister chromatids differentially stained by Giemsa after treatment with  $10^{-3}$  M thionin and 2 h exposure to sunlight. b, Same cell showing differential Feulgen reaction.

bound to the BrdU-substituted chromatids was quenched because the fluorescence efficiency of this dye bound to poly(dA-BrdU) was 20 per cent of that bound to poly(dA-dT)<sup>1</sup>. Ikushima and Wolff<sup>2</sup> and Perry and Wolff<sup>3</sup> considered, however, that this hypothesis is unable to explain their 33258 Hoechst-Giemsa method and supposed that the differential Giemsa staining is caused by binding of proteins. To test this possibility, chromosome specimens differentially stained with the above 33258 Hoechst-light-Giemsa method, after destaining in 0.01 M HCl, were treated with 0.01% trypsin in saline at the room temperature for 10–20 s (ref. 7) and restained with 2% Giemsa. This caused G-banding of the darkly Giemsa-stained chromatids but failed to re-establish the affinity of the dully stained chromatids to Giemsa dye. Therefore, proteins do not seem to be involved in the differential staining. On the other hand, Feulgen reaction<sup>4</sup> carried out on the specimens treated with 33258 Hoechst or thionin and exposed to light gave differential staining (Fig. 1b). This strongly suggests that BrdU-substituted DNA undergoes rapid photolysis in the presence of photosensitive dyes and strong light.

The exact mechanism of the photolysis is unknown. BrdU-substituted DNA, however, is susceptible to light and the BrdU-substituted DNA exposed to light and treated with alkali leads to breaks<sup>5</sup>. On the other hand, the fluorescence of 33258 Hoechst and acridine orange<sup>10</sup> is quenched in the presence of halogenated base analogues possibly by strong magnetic field of the halogen atoms<sup>11</sup>. Therefore, it is possible that the light-activated dyes situated near the base analogues may act as an alkali causing chain breaks and disorganisation of the chromatid DNA. Further studies with purified BrdU-substituted DNA is in progress.

## Thermolabile transfecting DNA from temperature-sensitive mutant of phage $\phi 29$

THE chromosome of bacteriophage  $\phi 29$ , one of the smallest *Bacillus* phages, is a non-permuted linear duplex DNA molecule of molecular weight  $11 \times 10^6$  (refs 1 and 2) that seems to be circularised by association with a protein, as circular monomers are converted into linear monomers by treatment with proteolytic enzymes<sup>3</sup>. A similar circular DNA-protein complex has been reported for adenoviruses<sup>4</sup>.

DNA extracted from phage  $\phi 29$  is infectious (transfectious) when added to competent cells of *B. subtilis*<sup>5</sup>. This transfectivity is sensitive to proteolytic enzymes<sup>6</sup>, indicating that some protein is associated with  $\phi 29$  DNA and is required for transfection. Protease-sensitive transfection has also been observed with DNAs of *B. subtilis* phages, GA1 (ref. 7), SPO2 and  $\phi 105$  (H. Hirokawa, personal communication).

The biological function of the  $\phi 29$  protein required for transfection is not known. It has been shown<sup>8</sup> that genetic markers on half- and quarter-length  $\phi 29$  DNA fragments can be rescued using competent cells super-infected with mutant phage, suggesting that DNA-bound protein is not essential for DNA uptake. It has also been shown that protease-treated GA1 phage DNA competes with transforming DNA to the same extent as untreated GA1 DNA<sup>7</sup>. Apparently the protein associated with phage DNA is needed at some stage of transfection other than uptake. Since a specific DNA-bound protein is required for transfection, one might expect to find transfection-defective mutants with altered DNA-protein complexes. Such mutants could aid in defining the role of the protein in DNA transfection. We show here that a temperature-sensitive DNA synthesis mutant of  $\phi 29$  originally isolated by Talavera *et al.*<sup>9,10</sup> produces thermolabile transfecting DNA.

Initially, we anticipated that mutant phages containing a thermolabile DNA-protein complex might be temperature-sensitive for viability. We therefore searched for a  $\phi 29$  mutant the viability of which was temperature-sensitive. One of the temperature-sensitive DNA synthesis mutants, *tsK132* (provided by Dr E. Viñuela) was found to be significantly more heat-sensitive than wild type (Fig. 1). Subsequently, we demonstrated that in transfection experiments *tsK132* DNA is also highly thermolabile. Kinetics of the loss of transfectivity as a function of time of heating at 65 °C are shown in Fig. 2. Since transfectivity of DNA samples was determined at 30 °C, the thermosensitivity of *tsK132* DNA is irreversible. Loss of transfectivity at a temperature lower than the melting temperature of  $\phi 29$

Fig. 1 Comparison of the heat stability of wild-type  $\phi 29$  (○) and *tsK132* phage particle (●). Phages ( $1 \times 10^8$  PFU ml<sup>-1</sup>) in phage adsorption medium (0.1 M NaCl,  $10^{-2}$  M MgSO<sub>4</sub> in 0.1 M Tris-HCl buffer, pH 7.0) were heated at 70 °C for the indicated times. After dilution, phages were titred at 30 °C using *B. amyloliquefaciens* H as indicator.

Fig. 2 Comparison of thermostability of transfectious DNA from wild-type  $\phi 29$  (○) and *tsK132* (●). Purified phage particles were disrupted by treatment with 1% Sarkosyl for 3 min at 40 °C. Transfectious DNA was phenol extracted and dialysed extensively against standard saline citrate in 0.01 M Tris-HCl buffer, pH 7.0, containing 0.1 mM EDTA. Each DNA solution (0.5  $\mu$ g ml<sup>-1</sup>) was heated for the indicated times and used for transfection. Transfectivity was determined at 30 °C using competent cells of *B. subtilis* 168 according to the method of Reilly and Spizizen<sup>5</sup>.

DNA ( $T_m$  86 °C)<sup>11</sup> suggests that this thermosensitivity results from an alteration in the protein associated with the DNA. The *K* gene of  $\phi 29$  is one of four genes acting on DNA synthesis early in infection<sup>12</sup>. Therefore, it was of considerable interest to establish that the same mutation affects both DNA replication and transfection.

DNA synthesis experiments were carried out to ascertain whether a purified reisolate of *tsK132* was temperature-sensitive for DNA replication. Thymine-requiring cells infected with phages were incubated in a medium containing tritiated thymidine and 6-(*p*-hydroxyphenylazo)-uracil (HPUra), added to inhibit host DNA synthesis<sup>9,13</sup>. Aliquots were removed at different times for determination of radioactivity in acid-insoluble material. Phage DNA synthesis in *tsK132*-infected cells is almost completely inhibited at 45 °C, whereas it is normal at 30 °C. A shift-up experiment was carried out to determine whether the temperature-sensitive function determined by the *K* gene is required continuously for DNA synthesis or whether it is completed at a definite time during the latent period. Cultures infected and incubated at 30 °C were shifted to 45 °C at different times and DNA synthesis was measured (Fig. 3a). Phage DNA synthesis in cells infected with the mutant stopped immediately when the cells were shifted from 30 to 45 °C. Therefore, the functional product of the *K* gene is required continuously for  $\phi 29$  DNA synthesis, and in mutant *tsK132* this product is inactivated immediately at 45 °C.

The results of shift-down experiments (Fig. 3b) indicate

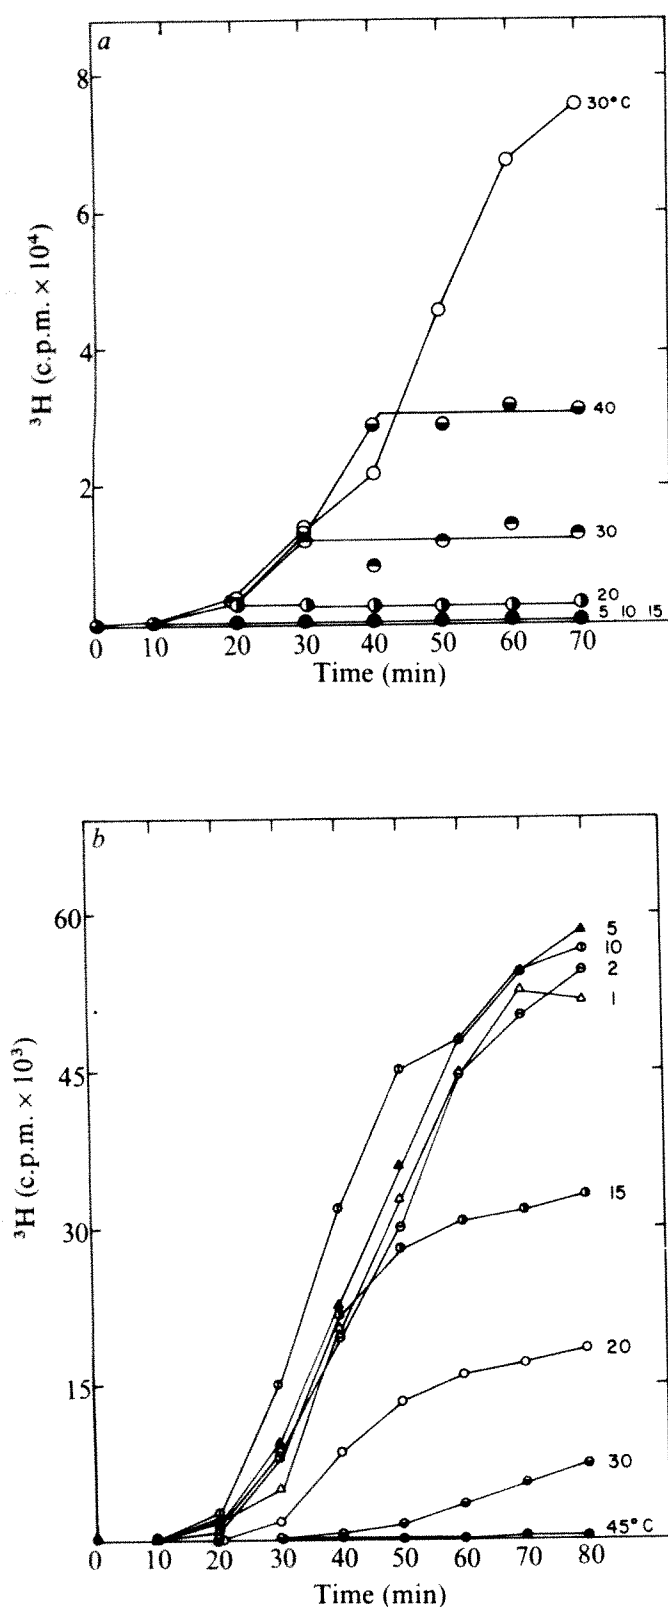

Fig. 3 Effects of temperature shift-up and shift-down on DNA synthesis in *tsK132*-infected cells. *B. subtilis* SCR 115 (*spoA12 thyA, B*) was grown to  $2 \times 10^8$  cells  $\text{ml}^{-1}$  in Penassay broth containing  $2 \mu\text{g ml}^{-1}$  thymine at 37°C, centrifuged, and resuspended in adsorption medium. Cells were mixed with phages at a multiplicity of 20 and incubated for 10 min at room temperature to enable adsorption. Bacteria-phage complexes were then transferred into  $^3\text{H}$ -thymidine incorporation medium consisting of Penassay broth,  $50 \mu\text{g/ml}$  HPURa and  $10 \mu\text{Ci/ml}$   $^3\text{H}$ -thymidine. Cultures were incubated with shaking at either 30°C(a) or 45°C(b). Infected cultures were shifted to the other temperature at the indicated times (min). Samples were removed, treated with 10% cold TCA, filtered, washed with 5% TCA-containing  $100 \mu\text{g ml}^{-1}$  thymidine and counted.

that shifts carried out up to 10 min after infection do not affect the ability of cells infected with *tsK132* to synthesise phage DNA. After this time, shift-down results in depressed levels of DNA synthesis. These results agree with those of Talavera *et al.*<sup>9,10</sup> in showing that mutant *tsK132* is deficient in DNA replication *in vivo*. Since both RNA and protein synthesis are required for  $\phi 29$  replication<sup>14</sup>, we examined the possibility that phage RNA synthesis is also shut off immediately after shifting the temperature from 30 to 45°C. RNA was extracted from *tsK132*-infected cells at various times after shifting from 30 to 45°C and hybridised to denatured  $\phi 29$  DNA immobilised on nitrocellulose filters. The results (not shown) indicate that phage messenger RNA (mRNA) synthesis is not blocked immediately after shifting from 30 to 45°C. Chloramphenicol added before the onset of DNA synthesis inhibits  $\phi 29$  DNA replication. It does not, however, shut off DNA synthesis immediately when added after 10 min of infection (not shown). These findings suggest that the immediate cessation of DNA synthesis in *tsK132*-infected cells at non-permissive temperatures is not secondary to an inability to synthesise phage-specific RNA or protein. Rather, it seems more likely that an essential component of the DNA-synthesising machinery is itself thermosensitive.

Reversion studies indicate that the *tsK132* mutant is a point mutation. In four isolated plaques of *tsK132* grown at 30°C, revertants appeared at an average frequency of  $5 \times 10^{-6}$ . Experiments with three *tsK132* revertants showed that they were indistinguishable from the wild type at 30 and 45°C in growth and thermostability of transfecting DNA. One of the revertants was crossed with the wild-type phage and 1,450 progeny phages were tested for temperature sensitivity. No *tsK132* segregants were found. We conclude that *tsK132* is a single-base change mutant and that reversion can occur at or near the site of the original lesion. Our results, therefore, together with those of Talavera *et al.*<sup>9,10</sup>, show that a single mutation affects both DNA replication and transfection. Consequently, it seems that at least one DNA-associated protein contained in the phage particle is involved in  $\phi 29$  DNA transfection. We have not yet identified the protein.

The possibility that the *K* protein is involved in circularisation of  $\phi 29$  DNA and that this is essential for transfection, seems remote since the circular protein-DNA complex of phage  $\phi 29$  can be disrupted by treatment with sodium dodecyl sulphate<sup>3</sup>. Such DNA is active in transfection (F. K. and J. I., unpublished). Another possible explanation for our results would be that the DNA-protein complex is resistant to attack by nucleases present in competent cells. Although this possibility cannot be ruled out, it also seems unlikely since protease-treated  $\phi 29$  DNA is able to rescue most of the genetic markers of  $\phi 29$  mutants (F. K. and J. I., unpublished).

Instead, in analogy with the *coli* phage M13 system<sup>15,16</sup>, it seems more likely that the  $\phi 29$  *K* gene specifies a 'pilot' protein essential for  $\phi 29$  DNA replication. The very same protein or a fragment thereof could be incorporated into the  $\phi 29$  phage particle during phage maturation as an integral protein which is required for  $\phi 29$  DNA transfection. Note that Ivarie and Pène<sup>14</sup> found that after infection parental  $\phi 29$  DNA is associated with host cell membrane. They described two mutants, one temperature-sensitive and the other suppressor-sensitive; both are unable to form DNA-membrane complexes and are defective in DNA replication<sup>17</sup>. Although the nature of the *K* gene protein and its function(s) are not known, further studies of this protein may clarify the role of DNA-associated proteins in DNA replication.

We thank Dr J. Spizizen for his encouragement, and Dr I. P. Crawford for discussions and Ms J. Ashwell for assistance. This research was supported by the NSF and the US Public Health Service. J.I. is the recipient of a Derr-

ham Senior Fellowship of the American Cancer Society.

## Involvement of DNA in resistance of potatoes to invasion by *Phytophthora infestans*

THE primary event that determines whether or not a plant becomes diseased is a mutual recognition which brings the plant into contact with the pathogen. Flor<sup>1</sup> developed the gene-for-gene theory from his studies of the relationship between flax and rust. This theory implies that the genes in the plant that condition the reaction can be identified only by their interaction with specific races of the pathogen, and the genes in the pathogen that condition pathogenicity can be identified only by their interaction with a specific cultivar of the plant. Allen<sup>2</sup> reported that nucleic acid or protein was involved in the resistance of the plant to the pathogen. Ledoux *et al.*<sup>3</sup> found that labelled DNA from bacteria could be incorporated into barley roots and become combined with the DNA in the nuclei of the plant cells. Thus DNA may have a role in the recognition of the plant by the pathogen. We have obtained support for this notion. We painted potato midribs and tubers with DNA fractions<sup>4</sup> from different potato cultivars and species of Solanaceae, and found that their susceptibility to *Phytophthora infestans* was affected.

When petiole midribs of potato cultivar Norin No. 1 (gene *r*, for susceptibility) were inoculated with zoospores of *P. infestans* (race 0), only lesions were observed, but when the DNA fraction of the resistant interspecific hybrid 96-56 (gene *R*<sub>1</sub>, for resistance) was applied to midribs of Norin No. 1, both lesions and hypersensitive flecks were found, and the cells invaded by the pathogen soon died (Fig. 1). Hypersensitive flecks are signs of premature dying off (necrosis) of the infected tissue as well as inactivation and localisation of the infectious agent, and are associated with the attack of a resistant plant by

Fig. 1 Lesions and hypersensitive flecks of late blight on potato tubers of Norin No. 1 painted with the DNA fraction of the hybrid. The DNA fraction was prepared by Thomas' method<sup>4</sup>. The concentration of DNA in the water solution was 455  $\mu\text{g ml}^{-1}$ . Painting was done with a sterilised brush. *P. infestans* was inoculated 1 h after painting. ●—●, Lesions (control); ○—○, flecks (painted tuber); ○—○—○, lesions (painted tuber).

incompatible races of *P. infestans*; lesions result from the invasion of a plant by compatible races of the pathogen.

Results were similar with tubers of hybrid 96-56 in contact with the DNA fraction of Norin No. 1, but the control (Norin No. 1, not painted with the DNA fraction of hybrid 96-56) had only lesions. On the tubers of hybrid 96-56 treated with the DNA fraction from Norin No. 1, both mycelia and conidia developed, similar to those observed in the control. The conidia on the hybrid tuber were  $25.9 \times 17.7 \mu\text{m}$ , somewhat smaller than those of the control ( $27.7 \times 18.1 \mu\text{m}$ ) (figures are the average of 50 conidia) (Fig. 2).

When petiole midribs of potato hybrid 96-56 were treated with the DNA fraction of tomato (cultivar Fukuju No. 2) both lesions and hypersensitive flecks were observed

Fig. 2 Mycelial growth of *P. infestans* on hybrid tuber painted with the DNA fraction of Norin No. 1. The concentration of DNA in the water solution was 457  $\mu\text{g ml}^{-1}$ . *P. infestans* was inoculated 1 h after painting.

‡72 h after inoculation of *Phytophthora infestans* (race 0).

(Table 1). Similar lesions and flecks developed when the petiole of Norin No. 1 was treated with the DNA fraction of jimson weed (*Datura abla* Nees) and tobacco (*Nicotiana tabacum* L. cultivar xanthi nc), but in the control (Norin No. 1 without painting the DNA of jimson weed and tobacco) only lesions were found (Table 2).

Electrophoresis revealed an increase in the amount of protein in the leaves of the susceptible cultivar after treatment with the DNA fraction from resistant hybrid, before it was inoculated with pathogen. A new protein band, coinciding in *R<sub>F</sub>* with a protein in the resistant hybrid, appeared 6 h after inoculation of an incompatible race of *P. infestans*. Potato leaves painted with the DNA fraction of different cultivars had more peroxidase and phenylalanine ammonia lyase activity than the control (without painting DNA).

\*The concentration of DNA in the water solution was 135 µg ml<sup>-1</sup>.

†The concentration of DNA in the water solution was 300 µg ml<sup>-1</sup>.

‡72 h after inoculation of *Phytophthora infestans* (race 0).

A large quantity of rishitin has been reported on the tubers of susceptible cultivars treated with the DNA fraction from the resistant hybrid<sup>6</sup>. Rishitin<sup>8,9</sup> is one of several phytoalexins, which were believed to be important for the hypersensitivity<sup>7</sup>. Rishitinol<sup>9</sup>, lubimin<sup>10</sup> and phytuberin<sup>11</sup> were also identified as phytoalexins in potatoes infected with *P. infestans*. Király *et al.*<sup>12</sup>, however, showed that this hypersensitive necrosis was a consequence, not the cause of resistance of potato, beans and wheat to various fungi. We have described<sup>13-16</sup>, however, the role of DNA fractions of potatoes in the creation of hypersensitivity to invasion by *P. infestans*. These and our results support the idea that DNA is directly involved in the specificity of fungal pathogen for the plants.

Details of this work will be published elsewhere. We

thank Dr Y. Miyazaki for seeds of jimson weed and tobacco.

## New class of enzymes acting on damaged DNA

ONE of the major pathways of DNA repair consists of the removal and replacement of damaged nucleotides in non-replicating DNA. In the classical excision repair model<sup>1,2</sup>, the first enzymatic step in this process is the introduction of a single-strand break in the DNA adjacent to a defective nucleotide residue. Endonucleases that specifically attack DNA containing pyrimidine dimers<sup>2</sup> or apurinic sites<sup>3-5</sup> have subsequently been isolated from many types of cells, and enzymes of these two types have been shown to be active in DNA repair in *Escherichia coli* by the isolation of repair-deficient mutant strains with defective endonucleases<sup>6,7</sup>.

An enzyme that specifically attacks DNA containing deaminated deoxycytidine monophosphate residues has also been detected in *E. coli*<sup>8</sup>. This enzyme is not, however, a regular nuclease, because it catalyses the hydrolysis of the N-glycosidic bonds of the damaged nucleotide residues, but it does not cleave any phosphodiester bonds. The reaction products after the action of this N-glycosidase on deaminated DNA are consequently free uracil and partly depyrimidinated DNA of unaltered chain length. Similar types of enzyme activities that release free 3-methyladenine (3-MeAde) and 6-methoxyguanine from alkylated DNA were discovered by Kirtikar and Goldthwait in a purified but non-homogeneous preparation of *E. coli* endonuclease II, and were ascribed to the endonuclease<sup>9</sup>. As the different DNA N-glycosidase activities may act together with endonuclease II in DNA repair, it seemed of interest to define the relationship of these enzyme activities to each other. In the present work, it is shown that the *E. coli* Ura-DNA glycosidase, 3-MeAde-DNA glycosidase, and endonuclease II activities are attributable to three different enzymes.

The three enzyme activities studied showed similar fractionation properties on streptomycin treatment, ammonium

sulphate fractionation, and gel filtration on Sephadex G-100 of an *E. coli* cell extract. On incubation at 45 °C of an enzyme fraction purified by these steps, however, the three activities were inactivated at different rates (Fig. 1). Endo-

**Fig. 1** Rates of heat inactivation at 45 °C of *E. coli* Ura-DNA glycosidase (■), 3-MeAde-DNA glycosidase (●) and endonuclease II (▲) activities. Activities were copurified from a crude cell extract of *E. coli* 1100 (endo I<sup>-</sup>) by streptomycin treatment, ammonium sulphate fractionation and gel filtration on Sephadex G-100 (ref. 8). Active protein fraction was dialysed against 0.2 M NaCl-0.05 M potassium phosphate (pH 7.4) and 0.001 M dithiothreitol, and aliquots were heated at 45 °C for indicated times before assay. Ura-DNA glycosidase was assayed by measuring the release of free uracil from partly deaminated DNA, initially radioactively labelled in the cytosine residues<sup>8</sup>. One enzyme unit releases 1 nmol uracil from DNA in standard reaction conditions. Endonuclease II was assayed by a modification of the method of Verly *et al.*<sup>4,16</sup>. One enzyme unit releases 1 nmol <sup>32</sup>P in acid-soluble form from the radioactive, partly depurinated DNA substrate in standard reaction conditions. 3-MeAde-DNA glycosidase was assayed by measuring the release of free 3-MeAde from alkylated DNA (ref. 9), as follows. *B. subtilis* DNA, <sup>14</sup>C-labelled in purine residues, was prepared as described previously<sup>17</sup>. DNA (0.3 mg ml<sup>-1</sup>, 4 × 10<sup>7</sup> c.p.m. mg<sup>-1</sup>) was incubated with 0.25 M methyl methanesulphonate in 0.1 M Tris-HCl and 10<sup>-3</sup> M trisodium citrate (pH 8.0) at 37 °C for 30 min. One-tenth volume 5 M NaCl and two volumes ethanol (chilled to -20 °C) were added at 0 °C, and the DNA fibres collected, washed in 80% ethanol, dissolved in 1 M NaCl, 0.01 M Tris-HCl and 0.001 M EDTA (pH 7.8), and dialysed for 16 h against the same buffer, followed by 3 h against buffer without NaCl. Alkylated DNA was stored in several small aliquots at -70 °C. This DNA contained 0.9% of the total radioactivity as 3-MeAde, as determined by paper chromatographic analysis of an acid hydrolysate in methanol-concentrated HCl-H<sub>2</sub>O (7:2:1, ref. 18). 3-MeAde was quantitatively released from DNA by incubation at 100 °C for 10 min at neutral pH (ref. 18). In enzyme assays, the reaction mixture (25 µl) contained 0.07 M HEPES-KOH (pH 7.8), 10<sup>-3</sup> M dithiothreitol, 2 µg alkylated <sup>14</sup>C-DNA and an amount of enzyme sufficient to cause 10-50% release of 3-MeAde. After 20 min incubation at 37 °C, mixtures were chilled to 0 °C and individually supplemented with 5 µl 0.5% 3-MeAde (Cyclo Chemicals), 3 µl 5M NaCl, 10 µl 0.2% heat-denatured calf thymus DNA and 90 µl ethanol (chilled to -20 °C). After 1 h at -10 °C, samples were centrifuged at 2 °C, and 100 µl supernatant were recovered. This material, which contained <3% initial radioactivity, was applied to a Whatman 3MM paper at room temperature (21 °C) and analysed by descending paper chromatography for 17 h in a system containing a saturated ammonium sulphate solution, 0.1 M phosphate (pH 7.2) and isopropanol (79:19:2, ref. 19). After drying, 3-MeAde spot was localised by its ultraviolet absorbance, cut into pieces and transferred to a scintillation vial, and eluted with 5 ml H<sub>2</sub>O for at least 1 h. Fifteen millilitres Aquasol (New England Nuclear) were then added, and the radioactivity was determined in a liquid scintillation spectrometer at a counting efficiency of 80%. One enzyme unit releases 1 nmol 3-MeAde in conditions described. In the absence of enzyme, 3% total 3-MeAde in the DNA was released by hydrolysis<sup>18</sup> during incubation. The identity of the enzymatically released material with authentic 3-MeAde was confirmed in three additional chromatography systems.

nuclease II activity was most heat-labile, with 50% of the activity remaining after about 100 s. 3-MeAde-DNA glycosidase activity was inactivated at a rate three times slower and had 50% residual activity after 5 min. Ura-DNA glycosidase activity remained practically unchanged after 12 min at 45 °C, but was inactivated at 55 °C with 50% inactivation occurring after 3 min.

Direct evidence for the notion that Ura-DNA glycosidase activity depended on a separate enzyme was obtained by the physical separation of this activity from the other enzyme activities investigated by hydroxyapatite chromatography. When the Sephadex-purified enzyme fraction was applied to a hydroxyapatite column in a buffer containing 0.01 M phosphate, Ura-DNA glycosidase activity did not adsorb and was recovered in the effluent. In contrast, more than 90% of the 3-MeAde-DNA glycosidase and endonuclease II activities adsorbed to the column but were eluted with 0.3 M phosphate buffer (Table 1).

It has been shown that *E. coli* endonuclease II and exonuclease III are the same enzyme, which has been assayed by different methods<sup>7</sup>. In agreement with this notion, a preparation of exonuclease III, made according to Jovin *et al.*<sup>10</sup>, contained a high level of endonuclease II activity.

**Fig. 2** Model for repair of partly deaminated or alkylated DNA. Complementary strand in DNA double helix not shown. a, Cytosine deamination (heat or bisulphite); b, release of free uracil (N-glycosidase); c, incision (endonuclease II); d, excision (exonuclease III); e, repair replication (a DNA polymerase); f, joining (DNA ligase).

In relation to the endonuclease activity, this enzyme preparation contained four fold less 3-MeAde-DNA glycosidase and 100-fold less Ura-DNA glycosidase activities (Table 1) than the much cruder Sephadex-purified enzyme fraction used here. This indicates that 3-MeAde-DNA glycosidase activity is partly removed and Ura-DNA glycosidase largely removed during the preparation of highly purified endonuclease II/exonuclease III by the above procedure.

In view of their specificities for damaged DNA<sup>8,9</sup>, it seems likely that the DNA N-glycosidases are active in DNA repair. A hypothetical model for such repair is shown in Fig. 2. It is proposed that for some types of DNA lesions (excluding pyrimidine dimers), the specific recognition and elimination of the damaged base is due to an N-glycosidase. The apurinic (or apyrimidinic) site is then repaired by the action of endonuclease II/exonuclease III, a DNA polymerase and DNA ligase<sup>3,15</sup>. One of the advantages of this

**Table 1** Relative amounts of Ura-DNA glycosidase, 3-MeAde-DNA glycosidase, and endonuclease II in different *E. coli* enzyme preparations

Enzyme fraction	Ura-DNA glycosidase (units mg <sup>-1</sup> )	3-MeAde-DNA glycosidase (units mg <sup>-1</sup> )	Endonuclease II (units mg <sup>-1</sup> )
<i>E. coli</i> 1100, Sephadex G-100 fraction	1,050	7.0	230
Hydroxyapatite fraction A	4,100	1.5	< 5
Hydroxyapatite fraction B	50	8.0	210
<i>E. coli</i> AB1157 ( <i>xthA</i> <sup>+</sup> ), Sephadex G-100 fraction	900	6.0	260
<i>E. coli</i> NH5016 ( <i>xthA</i> <sup>-</sup> ), Sephadex G-100 fraction	1,100	6.5	25
<i>E. coli</i> exonuclease III (ref. 10)	300	50	7,000

*E. coli* Sephadex G-100 fractions were made as described<sup>8</sup> (see also Fig. 1). For hydroxyapatite chromatography, an ammonium sulphate-concentrated Sephadex fraction (23 mg protein in 6 ml) was dialysed against 0.2 M KCl, 0.01 M potassium phosphate and 10<sup>-3</sup> M dithiothreitol (pH 7.4), and applied to a column (1.3 × 11 cm) of hydroxyapatite<sup>20</sup> in the same buffer. 20% of the protein did not adsorb to the column (fraction A). The adsorbed protein was then eluted with 0.3 M potassium phosphate (pH 7.4) and 10<sup>-3</sup> M dithiothreitol (fraction B).

Several methyl methane sulphonate-sensitive *E. coli* mutants, defective in endonuclease II, have been isolated (ref. 7 and S. Ljungquist, T. Lindahl, and P. Howard-Flanders, unpublished). An enzyme preparation from one mutant of that type, *E. coli* NH5016, was investigated here together with a preparation from the parent strain, *E. coli* AB1157. As expected, the mutant had a tenfold decreased amount of endonuclease II activity. In contrast, the same mutant extract contained normal levels of both DNA N-glycosidase activities (Table 1). The above data strongly suggest that *E. coli* 3-MeAde-DNA glycosidase and endonuclease II are two different enzymes, and it is clear that neither of them is identical with the Ura-DNA glycosidase.

It has been shown with both *E. coli* endonuclease II and the similar mammalian endonuclease acting at apurinic sites that alkylated DNA is not a substrate, unless the DNA is first incubated to enable release of alkylated purines by hydrolysis<sup>4,11</sup>. Goldthwait *et al.*<sup>12</sup> have claimed that the enzyme also acts directly on alkylated DNA. The finding of 3-MeAde-DNA glycosidase activity in partly purified *E. coli* endonuclease II preparations seems to explain this discrepancy, as the concerted effect of these two enzymes on alkylated DNA would be the introduction of single-strand breaks. Similar complications have arisen in the interpretation of data on enzymes degrading uracil-containing DNA. Carrier and Setlow<sup>13</sup> showed that an apparent endonuclease activity that acted specifically on uracil-containing DNA was present in *Micrococcus luteus* extracts, but their experimental design did not separate between enzymes that introduce chain breaks and enzymes that introduce alkali-labile sites. Tomita and Takahashi<sup>14</sup> reported that *Bacillus subtilis* contains a DNase specific for uracil-containing DNA, which released deoxyuridine as a major reaction product and was inhibited after infection with phage PBS1. The chromatographic method used to identify deoxyuridine, however, does not separate this substance from free uracil. Therefore, it seems unclear at present if conventional DNases exist that specifically attack uracil-containing DNA. Note that the Ura-DNA glycosidase seems to be a widely distributed enzyme that has so far been found in extracts from *E. coli*, *M. luteus*, *B. subtilis* and mammalian cells (T.L., unpublished).

scheme over the traditional excision repair model is that DNA ligase cannot act until the damaged nucleotide residue has been removed and replaced. A more definite assessment of the physiological functions of the DNA N-glycosidases, however, will have to await the isolation of mutant cell strains with defective enzymes of this class.

I thank Dr Bill Sugden for *E. coli* exonuclease III, and Ms Barbro Nyberg for assistance. This work was supported by the Swedish Natural Science Research Council, the Swedish Cancer Society and the Karolinska Institute.

*Note added in proof:* The rapid selective degradation of uracil-containing DNA by *B. subtilis* crude cell extracts is due to a Ura-DNA glycosidase. Extracts from phage PBS 2-infected bacteria contain a factor that completely inhibits the enzyme<sup>21</sup>.

# reviews

PTOLEMY'S (flourished AD 127–148) *Almagest* is a substantial and difficult work. Because it was the culmination of centuries of Greek astronomy, with its Babylonian background, and was the principal influence on astronomical theory up to the time of Copernicus and beyond, it has received the attention of every serious historian of astronomy. But, as Professor Pedersen says in his first chapter\*, "it has been talked about by many, but studied seriously only by the few." His aim is "to help students of the history of astronomy to understand and appreciate Ptolemy's great and classical work."

Since the mathematical and astronomical ideas of the *Almagest* are not very abstruse, the difficulties lie in the mode of presentation. Some of these difficulties were pointed out in the twelfth century by Jābir b. Aflah in his *Correction of the Almagest*. Among his many complaints, he said that the principles were obscured by numerical computations, that Ptolemy's exposition was sometimes too compressed, and that the meaning was often unclear because of the chain of translators between Ptolemy and himself. These defects Professor Pedersen has completely removed. He has elucidated the ideas behind Ptolemy's demonstrations, keeping them separate from numerical manipulations; difficult passages are examined in the light of recent scholarship; and, since he has worked from Heiberg's edition of the original Greek text, neither Professor Pedersen nor his readers have to suffer from the inaccuracies and obfuscations of translators.

Much of the clarity of this book comes from the author's ruthless use of modern notation. Not only are brackets, subscripts, square-root signs, and so on, used to describe the operations Ptolemy describes verbally, but some of his fundamental ideas are expressed in terms of functions, and some of his trigonometry is represented by the modern equivalent. Thus plane triangles are often solved in the modern way—that is, without dropping perpendiculars or circumscribing circles—and the functions *tan* and *cot*

\* *A Survey of the Almagest*. (Acta Historica Scientiarum Naturalium et Medicinalium, Volume 30.) By Olaf Pedersen. Pp. 454. (Odense University: Odense, Denmark, 1974.) Dn. kr. 200.00

## Ancient astronomical masterpiece

Ptolemy taking the altitude of a heavenly body with a quadrant (From G. Reisch, *Margarita Philosophica*, Basle, 1508)

are freely used where Ptolemy made do with chords. There is usually sufficient indication of what has been done. The result is that the reader knows that Ptolemy's exact mode of thinking has not been reported, but can see his line of reasoning without being distracted by the prolixities of archaic mathematical technique. It might be thought that modernisation is sometimes taken too far. On page 164, for instance, the mean longitude of the Moon is found by integrating its differential coefficient. While the reader may be assumed to realise that Ptolemy did not use the calculus, the modernity of the expression is startling and not really necessary. Elsewhere the anachronism is more than justified by the gain in clarity. For example, Ptolemy's calculation of lunar longitude from his general table is not easy to understand, but is fully explained in the *Survey* (pages 195–9) with the help of modern symbolism, particular attention being paid to Ptolemy's interpolative method of approximation. There are one or two mistakes in interpretation—I think, for instance, that the proof of the equivalence of the simple epicyclic and excentric models (pages 137–8) is mis-stated—

but such lapses are rare.

In some cases, Professor Pedersen goes beyond what is written in the *Almagest*, but only to make the meaning clear. Several graphs of relevant functions are included to make the astronomical model under consideration easier to understand. Further aids for the reader are to be found in Appendix B, in which all the numerical parameters calculated in the *Almagest* are collected, and in the lists of observations. Besides a general inventory of dated observations (Appendix A), the observational data for particular astronomical models are tabulated in the appropriate place in the text.

The purely historical content of the *Survey*, although not so compendious as the expository, provides a useful introduction to Alexandrian astronomy and physics. There is a short chapter on Ptolemy's other works; and his reliance, in the *Almagest* and elsewhere, on Babylonian and Hipparchan observations and parameters is discussed as they occur. The book is introduced by a chapter on the transmission of the *Almagest* up to modern times. It is completed by a large and useful bibliography.

R. P. Lorch

## Solar radiation

*Solar Gamma-, X-, and EUV Radiation.* (International Astronomical Union Symposium No. 68, Buenos Aires 1974). Organised by the IAU in cooperation with COSPAR.) Edited by Sharad E. Kane. Pp. xii + 439. (Reidel: Dordrecht and Boston, Massachusetts, 1975.) Dfl. 145; \$58.00.

DURING the past decade the rapid advance in instrumental techniques and the extensive use of orbiting observatories has provided a wealth of data on  $\gamma$ -, X-ray and EUV radiation from the Sun. The International Astronomical Union Symposium in June 1974 provided an opportunity for specialists in the field to review the observational results and to describe current theories of solar emission mechanisms and related phenomena. Highlights of the proceedings included reports of preliminary data from Skylab on the newly discovered coronal holes and bright points.

The book is split into three sections covering general solar activity, active regions and solar flares. Each section contains detailed review articles written

by leading authorities on the topics concerned, and summaries of contributed papers announcing the latest results. These include data from ground based telescopes, sounding rockets, balloons and satellites operated by American, European and Russian groups. In addition, the book contains papers on energetic particles and microwave radiation, forming a more complete picture of the solar phenomena in which they play a role. Thirty-nine papers are given in all.

The coverage of the rather broad subject suggested by the title is comprehensive, but inevitably in a collection of articles written independently by a large number of authors some duplication takes place and it is often difficult to refer to specific items of interest. The latter problem detracts a little from the value of the book as a reference volume for its intended audience of research workers and students in solar physics and solar terrestrial relations. Nevertheless, these workers will find it an important and necessary addition to the library of their respective research institutes, if a little expensive for their own bookshelves.

With the bulk of the Skylab data analysis yet to be completed and with the continued high level of activity in observational and theoretical solar studies it seems certain that this account of solar radiation will quickly be superseded. **C. G. Rappley**

but Lamarck comes in for much discussion.

I found some of the biochemical analogies in the book to be colourful, but perhaps not appropriate. For example, on page 268 the development of an egg into a vertebrate is likened to the proteolytic and lipolytic ripening of a cheese: "can develop as it were into a Cheddar, a Camembert, a Brie, etc., as well as into a Stilton".

Such an egg would become *pidan* rather than a duckling. The 'ripening' of cheese is not directed by the DNA inherently present, as in an egg. Ripening comes about by the degradative action of bacteria, as Waddington points out, by autolysis, or more usually by the growth of moulds. The "glory of ripeness" that he attributes to a Stilton cheese is the odour, taste and other properties of esters, fatty acids, and protein hydrolytic products that result from the decomposition of butterfat, lactose, casein and lactalbumin; a process that leads to putrefaction. What a contrast to the development of an egg—the fantastic spectacle of a DNA molecule at work to make another DNA molecule.

See also the description of protein structure on page 190, where the author says that all but "a small fraction of the amino acid chain" can be regarded as "packing or scaffolding and (has) not much more to do with the activity of the protein than had the scaffolding which allowed (the artist) to lie on his back... to paint the ceiling of the Sistine Chapel to do with the resulting artwork." This is probably an over-simplification of protein structure. For example, the enzyme, thermolysin, has a reactive site that is concerned with proteolysis, but the rest of the amino acid chain folds into a three-dimensional structure that permits only hydrophobic substrates to reach the reactive site.

Professor Waddington's discursions range across a wide scope of subjects, among them the evolution of developmental systems, adaptations, altruism, and language; genetic assimilation; canalising selection; the selection of environment *Drosophila* mutants; sexual isolation; archetypes in evolution; a catastrophe theory of evolution; and some interesting musings on "The human animal" and "The human evolutionary system"; and "Does evolution depend on random search?" His analysis of the "midwife toad incident"—a review of Koestler's book—is most entertaining.

The reader will find that Professor Waddington's book contains many fascinating excursions into evolutionary philosophy and into descriptions of the adaptations and special properties that make living organisms so enthralling to all of us. **T. H. Jukes**

MTP announce the publication of

## The Biology of Cancer

A new approach  
by Professor P. R. J. Burch

This book is a learned and closely-argued challenge to many current assumptions about the nature of malignant disease and the mechanisms of carcinogenesis. In particular it questions the widely-held presumption that smoking causes various cancers including lung cancer.

The book expounds and amplifies a theory of cancer and carcinogenesis that was first published in outline in *Nature* in 1970. A wealth of supporting evidence is cited from fields as diverse as molecular biology and clinical medicine.

This theory of cancer is the most detailed and comprehensive yet proposed: it also makes precise and testable predictions as well as suggesting some new approaches to the therapy of cancer.

## Evolutionary thoughts

*The Evolution of an Evolutionist.* By C. H. Waddington. Pp. xii + 328. (Edinburgh University Press: Edinburgh, May 1975.) £6.00.

PROFESSOR Waddington has reprinted twelve of his journal articles (five of them from *Nature*), and twelve excerpts by him from textbooks and symposia volumes. To these he has added two exchanges of correspondence (with T. Dobzhansky and P. M. Sheppard) and four book reviews. Two brief essays, not published elsewhere, are also included. The time span of the material reprinted covers from 1941 to 1974. Some of the subject matter is concerned with *Drosophila* genetics, and there is also a great deal of discussion of the differences between various trends of evolutionary thought.

I have a feeling that the question of the inheritance of acquired characters, so much a target of discussion and refutation by evolutionists, was dealt a mortal blow by the discovery of the molecular mechanism of protein synthesis. This point is not mentioned,

UNACUSTOMED as I am to watching television, it was with some diffidence that I agreed to review *The Human Conspiracy*, a programme that is part of a series intended sporadically to bring the latest scientific developments to your fireside. My experience while watching reminded me of those of a wealthy friend who always insisted on travelling first class. He had been brought up to believe that the most terrible goings on occurred in the second class and on the only occasion when he ventured to pass into that part of a ship, his worst expectations were confirmed. He wandered down a gangway and seeing an open door, entered a cabin just in time to cut down a passenger who had attempted to hang himself, doubtless driven to desperation by conditions in steerage. Whether this programme is typical of the BBC or whether it represents an isolated attempt at self destruction, it is not for me to say.

The programme consisted of a series of fragmentary episodes loosely organised around the theme of how men and women get to be the way they are. Viewers were shown psychologists in Belgium posing an impossible problem to a prisoner to assess his reactions, although just how this would help to determine whether he should be released was not made clear. A sequence showing a schizophrenic and her identical twin in Bergen led up to the misleading statement that "for schizophrenia it's two-to-one environment versus genes"—Ladbroke's please note. Malnourished children in Mexico were presented to demonstrate that starvation can lead to irreversible losses in intelligence. Liberian children have difficulty with mathematics, although their mothers are not surprisingly better at judging the amount of rice in a bowl than American college students. X-ray pictures of a foetus in the womb showed that babies are sensitive to their environment long before they are born. This sequence was duly followed by a picture of a baby being born but we were not told what this illustrated. We were then treated to innumerable shots of babies breast feeding, crying, following objects with their eyes, and, of more interest, howling at the sight of three simultaneous images of their mothers.

The second half concentrated on social interactions. Ron Moody donned a long nose to demonstrate that people tend to shun actors wearing false noses. Boys are more aggressive than girls, probably because they have more testosterone: so bring on a male chimpanzee displaying; and to illustrate that self-sacrifice is not merely a human virtue, why not have some soldier ants sacrificing themselves in defence of their queen? Robert Trivers discussed

the concept of reciprocal altruism which purports to explain why it is that men can be kind to people outside their immediate family: "if you scratch my back I'll scratch yours and therefore we shall both live to propagate our genes". Shots of poor whites in Pennsylvania and of Maori children illustrated the problem of being a member of a group whose identity is threatened, and the Trobriand islanders

## Missing connections

*The Human Conspiracy (BBC2, Saturday, December 6) set out to investigate new discoveries and theories about our personal and social behaviour. N. S. Sutherland here reviews the programme with some reservations. The still below shows presenter Caroline Medawar.*

were held up as a society free from class hatred and loneliness, and in which man's status depends on how much he gives not how much he takes, although how anyone gets enough in the first place to go on giving was never explained. Finally, war scenes were used to depict the idea that loyalty to a group may result in savage cruelty to out-groups, and the programme ended with the thought that "More than brotherly love, it's courtesy that makes the world go round".

Miss Caroline Medawar was the comère and very school-marmish she was: she gave the impression of having learned her lines carefully by heart and it is not clear whether her stilted intonation arose through failure to understand them or because she wished to dissociate herself from their silliness: she should perhaps be given the benefit of the doubt. The male commentators were more fortunate since they were spared the embarrassment of actually having to appear. Much of the visual material had little to do with the intellectual content and on the principle of shooting whatever moves, shifts to new locations were frequently accompanied by shots of motor cars.

I appreciate the difficulty of devising

a scientific programme intended for a general audience. The most successful attempts, to my mind, have been programmes introduced and informed by a single scientist with sufficient charisma to project his own personality: one example is the late Professor Korner's excellent series on molecular biology. Even where the contents are rather scrappy, as in Bronowski's *Ascent of Man*, the glimpse of an individual mind at work does something to provide a sustaining connection. I suspect that the producers of *The Human Conspiracy* have underestimated the intelligence and staying power of a general audience: a programme that concentrated on a single theme and made explicit the conclusions reached and the research methods used would surely be more gripping than one that makes a series of disconnected points none of which are developed in depth.

Moreover, the practice of taking all the examples from ongoing research is misleading, and gives the viewer a spurious impression that he is being presented with new conclusions: we were given no hint that research on in-groups and out-groups has been under way for many years and I could not grasp what new findings were expected to emerge from much of the current research shown. By limiting the programme to such research, the producers lose the opportunity to choose the study that best proves a point, where that study, as is usually the case, has already been completed. Finally, there can be no excuse for perpetrating scientific howlers. It was argued, for example, that since homosexuals cannot transmit their own genes, they only survive because they are of use to their immediate kin. There is, however, no evidence whatsoever that homosexuality is an inherited condition, and the argument is therefore vacuous.

I realise that the programme was not intended for readers of *Nature* and the writer, Nigel Calder, once claimed to follow Faraday in thinking that the "generality of mankind cannot accompany us for one short hour unless the path is strewn with flowers". This patronising remark captures the spirit in which the programme was devised, but even if it were true, some effort might have been taken to provide garlands in a healthy state of bloom rather than dead or wilting blossoms. I personally would have preferred a few brambles to relieve the bland and cosy monotony, typified by a sentiment expressed by Professor Jerome Bruner: "Isn't it clever of Nature to arrange that play like most other things in life doesn't work unless there's some fun in it". Ugh. □

## Awards

The Award Program in Cancer Immunology of the Cancer Research Institute of New York gave its inaugural prizes in October 1975 to: Dr Hans O. Sjogren, University of Lund, Sweden; Dr Robert J. Huebner, National Cancer Institute, Bethesda, Maryland; Dr Lloyd J. Old and Dr Edward A. Boyse, Sloan-Kettering Institute for Cancer Research, New York; Mr Edward J. Foley, Schering Corporation, Bloomfield, New Jersey; Peter A. Gorer (posthumous award); Dr Edmund Klein, Roswell Park Memorial Institute, Buffalo, New York; Dr George Klein, Karolinska Institutet, Stockholm, Sweden; Dr Richmond T. Prehn, University of Pennsylvania; Dr Gertrud Henle, Children's Hospital, Philadelphia, Pennsylvania; Dr Robert A. Good, Sloan-Kettering Institute for Cancer Research, New York; Mrs Helen C. Nauts, Cancer Research Institute, Inc., New York; Dr Donald L. Morton, University of California, Los Angeles; Dr Ludwik Gross, Veterans Administration Hospital, Bronx, New York; Dr Werner Henle, Children's Hospital, Philadelphia, Pennsylvania.

The British Pharmacological Society has awarded the Sandoz Prize in pharmacology to Dr J. Hughes of Aberdeen University for his pioneering work on encephalin.

The Dr H. P. Heineken Prize for 1976 has been awarded to Professor L. L. M. Van Deenen of the University of Utrecht for his research on the mechanism of action of phospholipases and on the structure of biomembranes.

## Appointment

Professor Yosef Aloni has been appointed the first Duckwitz Professor at the Weizmann Institute. The chair, for cancer research, has been established by the Federal German government in honour of Georg F. Duckwitz.

Philosophical Transactions of the Royal Society of London. B: Biological Sciences. Vol. 272, No. 915:

**The Medical Research Council's Steroid Reference Collection** has recently received a most generous gift from Professor T. Reichstein, Basel, of some four hundred samples from his extensive collection of steroids, which represents the results of forty years' research. Compounds in the androstane and pregnane series will be included in the next list of additions to the Steroid Reference Collection.

A large part of the gift consists of a unique range of derivatives of bile acids, of the types studied intensively for partial synthesis of adrenocortical steroids. These compounds range from the 'natural' bile acids of the C-24 (cholic acid) series, through nor-acids (C-23) and dinoracids (C-22), down to the etianic acids of the C-20 series. Within each series there are representatives of unsubstituted types, 3-, 11-, and 12-monosubstituted types, 3,7-, 3,11-, 3,12- and other disubstituted types, and finally 3,7,12-trisubstituted types.

Lists of these materials are available to workers who are interested and who can show a direct need for specific compounds; applications should be made to Professor W. Klyne or Dr D. N. Kirk at Westfield College, Hampstead, London NW3 7ST.

The amounts of material available in some cases are small, and many samples represent a considerable part of the world's supply of the compound. In these circumstances the Steroid Reference Collection must exercise restraint in the issue of such valuable materials.

**The Foulkes Foundation** invites applications for its 1976 fellowships. They are intended to finance science graduates taking a medical degree before doing medical research, or, similarly, medical graduates needing an additional science degree. Those interested should contact D. W. FitzSimons, Secretary, The Foulkes Foundation Fellowships, The CIBA Foundation, 41 Portland Place, London W1N 4BN.

## Time to speak out against cosy bilateralism

A YEAR and a half ago the governments of the United States and the Soviet Union declared that from March 1976 they would refrain from test-firing nuclear devices with yields of more than 150 kilotons. Atmospheric testing of devices of all sizes has been banned since 1963 (except that France and China never acceded to the treaty) but there has been a marked lack of enthusiasm among the nuclear powers for constraints on underground weapons tests. Now it looks as if even this modest bilateral measure may fail to materialise.

Testing of warheads has never been absolutely vital to a nuclear programme but there are obvious benefits in the regular, full scale firing of devices to try out new ideas. Weapons laboratories would find a total ban, if not unbearable, at least an inconvenience, and up to the present this has prevented really serious talk of a comprehensive treaty, in spite of regular pressure from non-nuclear powers who have seen the superpowers busily involved in 'upwards' proliferation while urging stringent controls against 'sideways' proliferation. For many years the vagaries of seismology were used to rule out a treaty—how could one go into an international agreement without adequate monitoring for violations? It will always be possible to deploy such an argument, of course, by insisting on lower and lower detection levels, but in recent years it has become clear that seismic monitoring capabilities are beginning to settle at a level at which a massive (and most unlikely) investment would be needed for further major advance.

When it became clear that the superpowers, under pressure to show at least some concern for the non-nuclear powers at the 1975 Non-Proliferation Treaty conference, were talking about a limited restriction, it was widely assumed that agreement would be reached on a level of about 50 kilotons (with which seismology could easily cope). When the figure of 150 kilotons was announced, there was general astonishment that anything so weak could seriously be proposed as an arms control measure. In hindsight, anyone who had seen the multi-lateral debates of the 1960s about strong arms control treaties give way to the bilateral SALT talks with their conveniently high ceilings should not have been surprised that the treaty had been designed to minimise inconvenience to the contracting parties. And the run-up to the treaty has allowed ample time for the testing of

larger devices—time which has been well used.

Unfortunately, two serious and entirely predictable problems have hampered the bilateral technical discussions thus far. The first is the difficulty in defining yield with any precision on the basis of remote measurements (the Soviet Union has consistently refused the United States access to any instrumentation on Soviet soil). The geological complexity of test-sites and the strange focusing and defocusing of seismic waves makes for uncertainties in yield determination of a factor of at least two, and the extensive East-West interchange of data in recent months does not seem to have brought much clarification.

The second problem is how to treat peaceful nuclear explosions. They have become very popular in the Soviet Union, which is thus unwilling to talk about even a 150-kiloton ceiling for its peaceful operations. If any doubted that warheads could be tested under a peaceful guise, India will have disabused them of that illusion. Ideally the devices would be supplied through an international agency from a stockpile, but if the International Atomic Energy Agency (IAEA) in Vienna has been approached to fulfil such a role it is being kept very quiet.

The omens are not good for the removal of these obstacles by March, but it is an election year in the United States and this tosses in many imponderables. If President Ford has to fight off a serious challenge from Mr Reagan he will probably wish to show he can be tough in foreign affairs—hence, no blind eye in treaties with the Russians, especially since Dr Kissinger has been so criticised for blind eyes to alleged SALT violations. But if President Ford wins the primary, a gesture of statesmanship before the election might well capture the public imagination (as President Kennedy found to his surprise after signing the Partial Test Ban Treaty).

Meanwhile the other nuclear and non-nuclear powers have to decide whether to raise a fuss in their forthcoming talks in Geneva about this cosy bilateralism. Some countries will. But how about Britain? Is it not time to drop the convention of not speaking against American initiatives, and to expose the treaty as a sham? Many people in high places in the United States might even be glad to have an old ally refuse to endorse a footling measure. □

The EEC countries have begun planning a more coherent approach to the exploitation of their joint energy resources. **Ray Dafter**, Energy Correspondent of the *Financial Times*, reports

## Examining Europe's energy equation

THE SO-CALLED energy crisis of 1973 and 1974 may, in retrospect, be viewed as a blessing in disguise for, if nothing else, it applied the minds of nations to something they had chosen to ignore for decades: the sensible planning of energy resources for the future. Cheap and plentiful crude oil, mainly from the Middle East, had followed supplies of cheap coal as the basic energy provider and it seemed that everyone had been lulled into a false sense of security. As Mr Frank Zarb, the US Federal Energy Administrator, pointed out in London recently, the industrialised world had paid dearly for its mistake.

The first world conference on energy and raw materials, held in Paris in December last year; the establishment of the International Energy Agency (IEA) by the OECD; the bid for a common energy policy within the EEC—all these are signs of a change in attitude to energy. The fact that the Paris conference produced very little in the way of solutions to the international problem is hardly surprising; the issues are both complex and fundamental. Similarly, it is understandable that the IEA and the EEC are making heavy weather of finding common energy policies; after all, member states are only just beginning to get to grips with their individual plans.

But progress is being made. The EEC Nine, for instance, have already agreed on restrictions on the use of oil and gas in power stations and on the maintenance of minimum stocks of fuel in case of another energy emergency. They are now firmly committed to an energy conservation policy and to a programme to replace imported oil with alternative fuels. It is anticipated, for instance, that even if the EEC economy grows at 4% a year over the next decade, conservation measures should keep the growth of energy requirements down to no more than 3%: a saving of perhaps 250 million tonnes of oil equivalent in 1985. (Last year energy consumption in western Europe was down some 15% on earlier forecasts although it is difficult to measure just how much of this was due to deliberate conservation rather than the general economic recession.)

New agreements also emerged from the stormy EEC summit meeting in Rome early in December last year and

*Oil: 'Already there is a feeling in the industry that the plums of the North Sea have been picked'*

Photo: J. Allan Cash

these could well prove to be the cornerstones of future European energy policies. For a start there now seems to be widespread acceptance, both in Europe and in the wider IEA, that there should be a minimum safeguard price for oil—in essence a safety net for producers like the UK and Norway should world prices tumble.

Second, Mr Harold Wilson's apparently ignominious stand-down from his demand for a separate seat at the Paris energy talks did persuade France to back an oil-sharing policy in times of crisis: surely a vital principle in any unified energy policy.

Now comes the task of putting shape and meaning to these general policies. The European Community has, as a basic aim, the intention of cutting its dependence on oil imports from the present 60% of energy requirements to around 50% and possibly 40% by 1985. Here the North Sea must make a timely and important contribution (which was why Britain was seeking its separate seat at the energy talks in the first place). By 1980 Britain should be producing between 100 million and 130 millions tonnes of oil a year, making it the only country in the EEC self-

sufficient in energy. By 1985 Britain's North Sea oil could account for around 45% of the Community's total energy output; put another way North Sea oil and gas could, by 1985, be satisfying up to 12 to 15% of the Community's energy needs. In addition, the North Sea could be providing a privileged source of imports from the Norwegian sector worth perhaps a further 5-7% of needs.

This is where the importance of a minimum safeguard price comes in. By 1980 some £5,000 million is likely to have been spent on oil exploration and development in the UK sector of the North Sea. This money (plus a great deal more on ancillary facilities) is being invested on the assumption that oil prices will remain high and provide a reasonable return. If for some political reason Middle East producers decided to slash the price of their oil—and their production costs are a fraction of those in the hostile North Sea—then Britain and the exploration companies will find themselves in deep trouble. As it stands, the 18 members of the IEA have agreed in principle to a floor price of \$7 a barrel, more than \$4 below the present market price but sufficient, in the Agency's eyes, to protect the development of alternative sources of energy.

And this is what it is all about—reducing the industrialised world's dependence on OPEC oil and encouraging the development of other energy providers. Here, the North Sea provides a useful stop-gap, but it would be foolhardy at this stage to over-emphasise its long term importance. Even on British Department of Energy estimates, reserves from proven fields are likely to last for only 10 to 20 years, though, of course, new fields are being discovered at an encouraging rate.

Professor Peter Odell, Director of the Economic Geography Institute at Erasmus University, Rotterdam, and an often-quoted authority on energy matters, feels that present and future trends in the North Sea offer "the possibility of a long term supply of indigenous oil capable of bringing the dependence of western Europe on foreign oil down to almost a derisory level."

Undoubtedly new commercial fields will emerge in the North Sea over the

next decade (a new licensing round in the British sector is planned for later this year). How commercial they prove to be will depend on their size, the ease of recovery and the closeness to existing fields (which should help transporting costs), as well as on the price of oil. Already there is a feeling in the oil industry that the plums of the North Sea have been picked.

In the short to medium term, oil and natural gas must inevitably play a dominant role in the EEC's energy use—around 64% of total use if the Community's plans come to fruition, a large proportion of these hydrocarbons coming from the North Sea. The importance of natural gas should not be underestimated—the EEC hopes to obtain at least 175 million tonnes of oil equivalent from member countries by 1985; if possible some 225 million tonnes. But what happens when these valuable resources start to dry up? It would be fanciful to predict that some of the more colourful ideas will fill the gap. True a lot of research is going into harnessing energy from waves, tides, the wind and the Sun. On paper many of these possibilities look attractive. For instance, the energy theoretically available from waves is immense—the equivalent to about 70 kW per metre on the Atlantic-facing coastline of Britain alone. The sheer cost and technical problems put such schemes well into the future, however.

Even if one adds in geothermal heat, which has received so much publicity recently, it is unlikely that these newer methods of raising energy will provide more than 6–8% of requirements by the end of the century—at least this is the conclusion of a Department of

Energy 'think tank' (Energy Technology Support Unit) set up in June 1974.

This, then, leaves nuclear power and the 'old faithful', coal, to fill any gap left by a fall-off in oil or gas; or at least to take up much of the energy growth over the next 25 years or so. In some ways this is a daunting prospect, for in Britain this implies an expansion by 20 times of the country's present nuclear capacity by the year 2000; daunting because it poses the problems of technology (which type of reactor should be used), lack of indigenous uranium resources, and public attitudes (the row in the UK over nuclear waste disposal cannot be ignored).

Looking further afield, on present projections nuclear power would need to provide the EEC with 16% of its energy requirements if the Community is to reach 60% self-sufficiency by 1985. This is a big leap from the 1.4% share provided in 1973. The more optimistic projections for the use of nuclear fuel put the amount of installed EEC capacity at 200,000 to 225,000 MW (electrical) by 1985 whereas even the ambitious national plans of member countries go no further than 160,000 MW.

All these problems highlight the folly of writing off the coal industry as outdated and unloved. The coal industries in both the UK and Germany are likely to be given a boost over the next few years. Britain, for instance, has just begun to plan for an expansion programme that could take its output back up to 200 million tonnes a year by the end of the century. (In the past decade output has fallen from that

Europe's Energy Commissioner,  
Henri Simonet

level to around 130 million tonnes a year.)

World resources of all types of coal have been estimated to be about 11 million million tonnes of which 700,000 million tonnes are known to be economically recoverable. But, coal or geothermal power, it is too early to assess with accuracy the relative importance of different forms of power even over the next decade. Policies are still emerging. But at least the industrialised world has learned the hard way that it must make the most of all available resources. It must be efficient in its use of energy, but above all it must be flexible. □

## Turkish poppy industry

### Straw cogs

*The results of Turkey lifting its ban on the cultivation of opium poppies may surprise the sceptics, argues Peter Collins*

THE Turkish Government seems to have scored a major success with its programme to control opium poppy cultivation and hence the illicit production of opium for the world's black market in drugs. Reporting on a visit to the poppy-growing areas at the harvest season, a United Nations official responsible for advising the Turkish government said that "no evidence could be found of opium production in Turkey in 1975". This should reassure those who may have had doubts about the Turks' ability to carry out their intentions, and confound certain United States senators and others who in 1974

foresaw America being flooded with heroin (the most dangerous opium derivative) when the Turks lifted their complete ban on opium poppy cultivation—a ban imposed largely because of pressure from the United States.

An important factor has always been that the Turkish farmers in the areas concerned have never grown poppies primarily as a source of opium, but rather for the seed and the oil derived therefrom which has traditionally been used as a normal part of their way of life. The Turkish government has prevented disruption of the local farming system by allowing the farmers to grow the poppies, though only on registered, and limited, areas. At the same time it has forbidden the lancing of the fruiting capsules, which must be done to get the opium. By harvesting the poppy straw (as the rest of the plant is called) as a monopoly, the government has also been able to continue supplying the world's pharmaceutical trade with the

raw material from which codeine, and hence various other materials, are extracted. All this has helped avoid a world shortage of codeine as well as cut off a potential source of illicit heroin.

No one expects a major programme like this to be a total success immediately. At least one of the problems raised could hardly have been foreseen. During an inspection tour of the growing areas, the UN team found that the government measures were if anything being too harshly applied. The areas that farmers had been allowed to sow were laid down in hectares, and a considerable number of farmers were found to have sown more than the area for which their licences allowed. The local farmers, it seems, think in terms of the dunum, an area which is actually slightly larger than the decare (1/10th of a hectare). Although this was a genuine mistake, understandable in a country where almost every region has

a local system of weights and measures, the law was extremely harsh on these men. Nor could any respite be obtained for them when the UN team pointed out that the excess area planted was in fact very small, and that officialdom as much as growers had made a mistake. The official argument has been that the arrest of the offenders will emphasise that the government really does mean business, and that to release them will bring the law into disrepute. Each must wait till the law has run its course; but if he can show that a mistake was genuinely made, he will eventually be released and granted a licence to grow poppies again, which would not otherwise be the case.

Meanwhile, the area any one farmer may cultivate has increased to a maximum of 5 decares from the permitted area in 1975 of 2 decares, which many farmers considered was too small to

be worthwhile. But it looks as though most of the farmers who have suffered arrest will not have had their cases heard in time for this year's sowing.

As far as the mechanics of the control system are concerned, the government programme seems to have been well organised and implemented. A number of 5-man teams were set up to inspect and control cultivation, and they are backed by 80 teams of gendarmes for detailed inspection. Vehicles for these teams have been provided through UN funds, and the same source of finance is being used to set up a telecommunications network between such major centres in the poppy-growing area as Afyon and Konya and the mobile inspection teams.

Other UN assistance is directed towards providing equipment for laboratories in Turkey for morphine

detection, carrying out training in this field at the Narcotics Laboratory in Geneva and training law enforcement personnel. The funds have also been used initially to underwrite a good guaranteed price for farmers. In 1975 they received 17 Turkish lira a kilogram for poppy "straw" and retained the seed which is their main interest. Although research is in hand to evolve more productive varieties of poppy in terms of both seed and morphine content, it is also hoped that eventually more farmers will turn to other crops, in accordance with official plans for the overall development of the areas concerned. Finally, plans are well advanced, again with UN advice and assistance, for the establishment within Turkey of a processing plant to handle the poppy straw which is now the main export product of the former opium-producing region. □

THE energy plan proposed last summer by the Minister for Industry, Sr Donat-Cattin, was approved on December 23 by the CIPE, the inter-ministerial committee for economic programming. The crux of Sr Donat-Cattin's plan is to supplement the three nuclear power stations already in existence with twenty or more by 1985, which will double the country's electricity production capacity.

In the heated debate over the plan this autumn, one of the most frequent criticisms has been that Italy will simply replace its dependence on the oil-producing countries with one on the uranium-producing countries, without gaining anything. It is also felt that the tremendous increase in capacity, which assumes growth of 4-5% a year, is unnecessary. The electricity board (ENEL) has countered this by pointing out that in the sharp recession of 1975 consumption decreased by only 1% of 1974 consumption, and claims that its plans are flexible enough to be adjusted in the future if necessary.

The US companies Westinghouse and General Electric are to build the 1,000 MW water-cooled reactors, and this has not pleased the Italian trade unions. Italian companies would, in fact, have been capable of doing a large part of the construction work, greatly relieving the balance of payments burden and the unemployment problem. And of course there are the worries about the safety of the US reactors.

A miniature and more furious version of the national debate has been going on in Lombardy, where Sr Donat-Cattin wants sites for two of the reactors to be found. The

regional government wants only one reactor. Instructed by the central government to find one site on the Po near Mantua and another near Lake Como, it has missed the deadline for doing either. The central government now has to choose.

## Letter from Italy

from Gillian Boucher

● What elsewhere has been reported as Italy's blocking of the EEC project for nuclear fusion research has been seen in Italy as resistance by the other EEC countries to the Italian site for the project, Ispra. The EEC Commission felt Ispra to be the most suitable site for the experimental thermonuclear plant, the Joint European Torus (JET); led by the Minister for Science, Sr Pedini, to believe that the decision was virtually final, Italians were startled by the inability of the research ministers to agree about it when they met in Brussels in December.

As enumerated by the Commission, the advantages of Ispra over its competitors—the chief of which is

Culham in the UK—include its connections with Euratom, abundant electricity, available skill, experience of safety measures, and a pleasant environment (on the shores of Lake Maggiore) with an international school. Fears that work may be interrupted by labour problems seem exaggerated; Ispra has suffered industrial action in the past, but in 1975 only 34 hours were lost through strikes. The Euratom link, however, is not an entirely positive attribute: Ispra has constantly suffered from a lack of proper organisation and last summer faced a crisis which only a special grant of 2,000 million lire from the EEC averted. If it does not win JET its future looks extremely uncomfortable.

● After centuries of shooting anything that flutters or cheeps, the Italians have suddenly become wildlife-conscious. A bill on hunting has just been approved by the Senate; when the Camera, or House of Deputies, has approved it, it will provide general principles to guide regional governments in drafting their own rules.

According to the bill anyone who wants a gun licence will in future have to pass an examination on the applied biology and zoology of hunting, the law on hunting, firearms and how to use them, and conservation. Italians wishing to shoot will be required to take out third-party insurance, a protection which can hardly make them more carefree about where they point their guns than they are at present. Wildlife reserves will be established, and what may be shot where, when, and in what numbers will be specified in detail.

## The Loch Ness Monster

SIR,—In their recent article entitled "Naming the Loch Ness Monster" (*Nature*, December 11) Scott and Rines propose formal generic and specific names for a rhomboidal object photographed in Loch Ness. They fail, however, to demonstrate with any conviction that the object is animate, that it shares anything with the later photograph showing two very differently shaped images, or that there is any basis whatever for their suggestion that it represents a species of reptile.

One of the great achievements of eighteenth century zoologists was to devise a disciplined system for the description and naming of animals, one result of which was effectively to distinguish between the real and the mythical animals of earlier writings. The code of nomenclature that has been developed over the succeeding years has been very carefully designed to adjudicate only with regard to the choice of names, thereby avoiding any restriction of freedom in the interpretation of zoological evidence. The onus is therefore on authors and editors to maintain standards of description and rational argument to prevent a return to the days of uncritical mythology.

Readers of *Nature* might reasonably expect an article presenting and interpreting original taxonomic data to have been subjected to the normal refereeing process. The evidence presented for the existence of *Nessiteras rhombopteryx* as a new species of animal falls far short of any normal standards expected in taxonomic zoology, even allowing for the preliminary nature of the report. No details are given of the 'optical data' by which the sizes of the objects were determined, nor of the technique by which the first two photographs were determined, nor of the technique by which the first two photographs were 'computer-enhanced'. No mention is made of controls showing how familiar objects appear on film and sonar traces under the same conditions. These will presumably be included when the observations are published in more detail, but meanwhile it is inconceivable that the application of a name in these circumstances can serve the authors' objective of promoting the conservation of any large animal that might subsequently be found in Loch Ness.

Biologists daily encounter pheno-

mena that they cannot identify or explain. It happens every time a field ornithologist fails to identify a distant bird. He will normally prefer to explain his failure in terms of the limitations of his expertise, the poor atmospheric conditions or the extreme distance, rather than jump to the conclusion that it must be an undescribed species of bird. This analogy is very relevant to a great diversity of so-called unexplained phenomena in Loch Ness.

Zoological taxonomy and scientific publication in Britain have both achieved high reputations. It is a pity to jeopardise these reputations for no good cause. It would be an exciting day for all zoologists if convincing proof were to be produced of a new large animal in the zoologically best explored country on Earth. This paper is unlikely to persuade the scientific community that that day has arrived although it may well serve to mislead the layman into believing that it has.

GORDON B CORBET

Department of Zoology,  
British Museum (Natural History),  
London SW7, UK

### Sir Peter Scott replies:

G. B. Corbet, referring to a rhomboidal object shown in two photographs in the article "Naming the Loch Ness Monster", claims that its authors "fail to demonstrate with any conviction that the object is animate" by which no doubt he means that he is not convinced. Others with equal claims to scientific objectivity have expressed an opposite view, being impressed by the slight difference in the configuration and the orientation of the flipper shown by the pictures, taken one minute apart by a fixed camera on the bottom, which clearly shows that the structure cannot be rigid.

Dr Corbet chooses to ignore the simultaneous sonar evidence with its clear indication that moving objects of large size were present at the time the photographs were taken. He says we have failed to demonstrate "that there is any basis whatever for the suggestion that it represents a species of reptile". We explain that we believe the flipper belongs to a vertebrate animal and that no known aquatic mammal has such a limb. It has not been possible to attribute the shape to any known fish or amphibian; on the other hand, the shape conforms rather closely with the limbs of certain fossil reptiles. In spite

of his analogy which refers to "an undescribed species of bird", it seems unlikely that Dr Corbet would prefer to attribute the Loch Ness Monster to that class. The actual quote from the article is "the inclination is to view it as reptilean".

The objective of the paper was quite clearly stated in the preamble: "Better to be safe than sorry; a name for a species whose existence is still a matter of controversy among many scientists is preferable to none if its protection is to be assured". I do not know what particular expertise Dr Corbet may have for asserting that the objective will not be achieved. Meanwhile it seems sad that he is working so hard to prevent it.

\* \* \*

SIR,—The publication of Scott and Rines and the photographs in the national press indicate that there may be a plesiosaur-like reptile inhabiting Loch Ness. It is exceedingly difficult to envisage how a former tropical marine reptile could endure the cold waters and harsh environment provided by a small lake in Scotland. Since Loch Ness did not exist until some 12,000 years ago, one is faced with the problem of the survival of 'Nessiteras' for a period of 64 million years in a world where its former ecological niche had been occupied by modern cetaceans and pinnipeds.

A certain amount of research on the functional anatomy of plesiosaurs has been undertaken and the results widely reported\*. There were two major types: the long-necked which fed on fish in the surface waters, and the streamlined large-headed forms which fed on cephalopods and were capable of diving to depths of 300 m. The postulated shape of 'Nessiteras' is reminiscent of the non-diving surface living variety; the postulated behaviour is of the large-headed short-necked forms. The evolutionary history of both groups of plesiosaurs can be traced for a period of 150 million years with very minor changes being recorded. It is inherently improbable that from such a stock this strange mixture of both groups would suddenly emerge.

The three key pieces of photographic evidence, which purport to show the neck and part of the body, the right hind flipper and the head, deserve to be analysed in the context of the accumulated knowledge of both living

and extinct aquatic reptiles and other water-dwelling air-breathers. The only way that the neck and body picture could be restored to form a plesiosaur would be to cover a skeleton with skin, but with the musculature reconstructed a different shape would be produced. The appearance of a truncated 'limb' and its negative on the opposite side of the 'body', together with other rectangular areas, would seem to exclude any possibility of this structure being reptilian.

Fig. a Hydrofoil limb of *Plesiosaurus* to show extent of soft tissues (after Robinson 1975).

Fig. b Oar forelimb of '*Nessiteras*' to show axial 'skeleton' (after Scott and Rines 1975).

The correct shape of plesiosaur flippers is rarely illustrated, but it has been known since Dames described skin impressions in 1895. The bones were situated along the leading edge with a tapering fleshy trailing edge; the plesiosaur limb was hydrofoil-shaped (Figs a and b). The limbs of plesiosaurs functioned in the same way as those of marine turtles, penguins and sea lions. The type of fin described by Scott and Rines is not known to exist in any marine vertebrate to our knowledge. It is not a hydrofoil but instead is oar-shaped. There is a central axis and the distal end tapers to a point thus reducing drag. It is inconceivable that an animal with efficient hydrofoil limbs should dispense with them for inefficient oars.

The heads of marine reptiles have their nostrils situated immediately in front of the orbits (the crocodiles are the exception to this but they have achieved the same functional end by evolving a secondary palate). Furthermore, the heads are streamlined. In contrast to this, the photograph of the Loch Ness head has terminal nares with the nasal region being clearly marked off from the orbital by a pronounced ridge or step. There even appear to be horns growing from the frontal region. There is no hint among any group of reptiles of such quasi-mammalian contours.

The evidence claimed to establish

the existence of an aquatic reptile '*Nessiteras rhombopteryx*' allows of an alternative and more logical interpretation.

The 'body-neck' photograph could be of the prow or stern of a Viking ship; the positive and negative projections would be transverse cross-beams of the hull; the longitudinal rectangle would be one of the main planks. It is perhaps worth noting that there are records of Viking raids on ancient settlements in the region of Loch Ness, for example Iona.

Mr Sheridan has already pointed out (reported in *The Times*) the similarity of the 2m long right hand fin to the steering rudder of Viking ships, which is always situated at the starboard stern (posterior right-hand side). Finally the head photograph is exceedingly similar to the dragon heads with which the Vikings embellished the prows of their vessels (and royal furniture). The Loch Ness head would appear to be generically related to the Oseberg head in Oxenstierna's *The Norsemen*.

The features attributed to the new taxon *Nessiteras rhombopteryx* are inconsistent with the anatomy and inferred functioning of any group of extinct reptile. The conclusion seems inescapable. Scott and Rines have discovered the remains of a Viking ship and have mistakenly interpreted them in terms of a living organism.

L. B. HALSTEAD

P. D. GORIUP

J. A. MIDDLETON

Departments of Geology and Zoology,  
University of Reading, UK

\* Watson, D. M. S., *Proc. zool. Soc. Lond.*, 885 (1924); Tarlo, L. B., *Palaeontology*, 1, 193 (1958), *ibid.*, 2, 39 (1959); *New Scientist*, 1414 (1960); Newman, B. H., and Tarlo, L. B., *Animals*, 10 (2), 61 (1967); Halstead, L. B., *The Pattern of Vertebrate Evolution*, 132 (Oliver and Boyd, Edinburgh, 1969); Halstead, L. B., and Middleton, J. A., *Bone bones—an exploration in art and science*, 29 (Oliver and Boyd, Edinburgh, 1972); Robinson, J. A., *N. Jb. Geol. Paläont. Abh.*, 149, 286 (1975); Halstead, L. B., *The evolution and ecology of the dinosaurs*, 68 (Peter Lowe, London, 1975).

Sir Peter Scott replies:

Your correspondents Halstead, Goriup and Middleton argue interestingly that plesiosaurs were either long-necked and lived in shallow water eating fish, or short-necked and dived to 300m to catch squids. They claim that the behaviour of *Nessiteras* (of which we know very little) living in a loch that is 300m deep, but being long-necked, is "a strange mixture of both groups" and therefore "inherently improbable." But in many animal orders whose evolution displays adaptive radiation we find primitive types surviving among the more advanced. To discover features of two known groups combined in one species does not necessarily postulate reticulate evolution.

I agree with your correspondents when they say "it is inconceivable that

an animal with efficient hydrofoil limbs should dispense with them for inefficient oars." But how do we know that the ancestors of *Nessiteras* ever had efficient hydrofoil limbs, and who is to measure the efficiency of their diamond-shaped flippers against the functions they have to perform? Evidently it is adequate for their mode of life.

It may be worth remembering that scores of species of some 53 genera of plesiosaurs are known to science from their fossil bones. In none of them is the skin contour of the head recorded in the stone, and only two examples show the skin contour of the flippers. In many cases the shapes of both birds' wings and fishes' fins vary widely within a single order.

Nor should we forget the processes of convergent evolution. Our paper describing *Nessiteras* said of the flipper "the inclination is to view it as reptilian." Nowhere in the paper was the name plesiosaur used.

The theory that the photographs depict the remains of a Viking ship does not fit the facts, even if the vessel were to be drifting round in midwater like a submerged Flying Dutchman. It is quite impossible, within a number of limiting circumstances, for the head photograph to be a stationary object attached to, or resting on the bottom. These limitations include the geometry of the camera, its strobe-flash equipment and the rope from which it was suspended from the boat, the distance and nature of the bottom below, and the turbidity of the water. On the other hand the Dragon head from Oseberg which they show may, in spite of its mammalian connotations, perhaps have been influenced by monsters well known to the Vikings.

The interpretation of the two pictures of the flipper as a rudder of a Viking ship is perhaps a measure of the inadequacy of modern newsprint reproduction. In the enlargements of the computer-enhanced photographs it is especially interesting that, in the interval of one minute between exposures in a camera standing stationary on the bottom, the flipper has changed shape and orientation. The changes are entirely consistent with the movement of an animal's swimming limb, and could not conceivably have happened if the object had been fixed and solid. These photographs were taken simultaneously with the moving objects shown in the sonar trace published with our article, which seem to have been conveniently ignored by your correspondents. They end with "an inescapable conclusion" from which they might do well to escape after all. If they are interested in Viking ships they will have to go elsewhere to find them.

## Terminators and attenuators

from Andrew Travers

POSITIVE control of early gene expression in phage  $\lambda$  requires the function of  $\lambda$  N protein. This regulator permits the transcription of  $\lambda$  early genes yet its sites of action are clearly distal to and distant from the early  $\lambda$  promoters. There is, however, a striking correlation between these sites and transcriptional terminators whose efficient function *in vitro* requires the protein  $\rho$ . From this evidence Roberts (*Nature*, **224**, 1168–1174; 1969) proposed that N antagonised  $\rho$  function and thus allowed these termination signals to be overridden with a consequent extension of the RNA chains initiated at early promoters.

A further insight into the role of  $\rho$  *in vivo* came with the observations that there are  $\rho$ -sensitive terminators within the *gal* operon and that mutant *gal* operons containing polar insertions are also polar *in vitro* in the presence of  $\rho$  (de Crombrughe *et al.*, *Nature new Biol.*, **241**, 260–264; 1973). This suggested that natural polarity of bacterial operons might be a consequence of  $\rho$  function. Another example of transcriptional polarity, that induced by nonsense and frameshift mutations, can be suppressed by second site mutations within the *suA* gene. These mutations, which are recessive to the wild type allele, partially relieve the polar effect of the original mutation without altering the termination of protein synthesis induced by that mutation (Morse and Primakoff, *Nature*, **226**, 28–31; 1970). This parallel between the *in vitro* effect of  $\rho$  in inducing polarity and the *in vivo* effect of *suA* mutants in relieving polarity raised the possibility that  $\rho$  might be the product of the *suA* gene.

Earlier this year this possibility received strong support from observations of Richardson *et al.* (*Proc. natn. Acad. Sci. U.S.A.*, **72**, 1725–1728; 1975). They found that  $\rho$  factor purified from a strain containing the *su78* mutation in the *suA* gene has altered termination function. This  $\rho$  factor fails to terminate transcription at some sites that are efficiently recognised by  $\rho$  factor purified from an isogenic wild type strain. Moreover, a second

*suA* mutation reduces the recovery of  $\rho$  activity from crude extracts by more than 90%. These results do not in themselves prove that  $\rho$  is the product of the *suA* gene, since mutation in that gene could indirectly affect  $\rho$  activity. They do show, however, that termination factor activity is altered in strains containing a polarity suppressor thus again implying that  $\rho$  is involved in transcriptional polarity.

The connection between  $\rho$  function and polarity allowed two predictions to be made. First that polar mutations in bacterial operons might be overcome by active  $\lambda$  N protein. Second that  $\lambda$  N gene mutants which are unable to grow because of their failure to produce sufficient  $\lambda$  early mRNA should themselves be rescued by polarity suppressors. Both predictions have now been verified. N gene function overrides polar mutations in the *gal* and *trp* operons (Adhya *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **71**, 2534–2538; 1974; Franklin, *J. molec. Biol.*, **89**, 33–48; 1974; Segawa and Imamota, *J. molec. Biol.*, **87**, 741–754; 1974) but only when transcription is initiated at a  $\lambda$  promoter *in cis* to the bacterial genes. This implies that N function requires a phage specific site in order to alter the properties of the transcription complex. The experimental approach to test the second prediction was the direct selection of bacterial mutants which specifically suppress  $\lambda$  N mutants (Brunel and Davidson, *Molec. gen. Genet.*, **136**, 167–180; 1975). These bacterial mutants, designated *sun*, map very close to the known map position of *suA*. Moreover the *sun* mutants are themselves able to suppress polarity in a bacterial operon, albeit only weakly. Conversely one *suA* mutant exhibits a *sun* phenotype. All these results suggest that *sun* and *suA* are allelic. If the only major role of N protein is to antagonise  $\rho$ , *suA* gene function is thus again linked to  $\rho$  activity.

To what extent is the antagonism of transcriptional termination by N protein a specific example of a more general mode of controlling gene expression? Two recent findings suggest that the phenomenon may be wide-

spread. Roberts, together with Sklar *et al.* (*Proc. natn. Acad. Sci. U.S.A.*, **72**, 1817–1821 and 3300–3304; 1975), has provided evidence that the synthesis of  $\lambda$  late mRNA may be controlled in a similar manner to early  $\lambda$  mRNA. They show that a transcription terminator occurs between the promoter for late gene expression and the late genes themselves. This terminator results in the *in vitro* production of a small RNA species about 200 nucleotides long. Late  $\lambda$  mRNA synthesis is under positive control of gene Q and Roberts proposes that the Q gene product acts in a manner analogous to N protein. If this is so it follows that anti-terminator proteins may differ in specificity.

Nor is the positioning of a terminator closely distal to a promoter exclusive to  $\lambda$ . Bertrand *et al.* (*Science*, **189**, 22–26; 1975) have described a strikingly similar structure in the *E. coli trp* operon. The existence of a terminator close to the *trp* promoter was first suggested by the properties of small deletions between the *trp* promoter-operator region and the first structural gene in the *trp* operon. Such deletions produce elevated levels of both *trp* mRNA and polypeptides yet the *trp* repressor-operator interaction is unaffected by the deletion. This effect is *cis*-dominant. Analysis of the RNA produced *in vivo* and *in vitro* from the region immediately distal to the promoter reveals a major RNA species 130 nucleotides long corresponding to the 5'-terminal sequence of the normal *trp* mRNA. *In vivo* the extent of termination resulting in the production of this RNA is regulated. In particular tryptophan deprivation results in relaxation of termination with a corresponding increase in the levels of *trp* mRNA and polypeptides produced. Bertrand *et al.*, propose that the terminator site may function to govern the fraction of initiated polymerase molecules that will transcribe the entire *trp* operon. The control is thus a quantitative modulation rather than a strict on-off switch and accordingly the authors suggest that this DNA signal for termination be termed an 'attenuator'. Other evidence indicates that similar atten-

uators may control expression of the *E. coli ilv* operon and the *S. typhimurium his* operon (Kasai, *Nature*, **249**, 523-527, 1974).

The parallel between the *trp* attenuator and  $\lambda$  terminators overridden by N function is strengthened by the finding that polarity suppressors allelic to *suA* partially relieve attenuation. The original *suA* mutants are, however, relatively inefficient in this respect. Again different alleles of *suA* differ in their effectiveness at suppressing polarity at different terminators. The ubiquitous association of *suA* mutants with a failure to terminate transcription coupled with the selectivity of different *suA* alleles argues that  $\rho$  may indeed be the product of the *suA* gene.

This strong suspicion is confirmed by two observations of Ratner (this issue of *Nature*, page 151). First, affinity chromatography analysis of  $\rho$  protein from different *E. coli* strains reveals that different *suA* mutations affect  $\rho$  in disparate ways: one destabilises  $\rho$ , a second apparently increased the molecular weight of the polypeptide, while others which are presumed to be missense mutations overproduce  $\rho$ . Finally by making use of a molecular weight difference between  $\rho$  isolated from different *E. coli* strains Ratner shows that the  $\rho$  gene is tightly linked to the *suA* locus. Together these experiments make it almost certain that the *suA* locus defines the structural gene for  $\rho$  and not a modifier of  $\rho$  protein.

decreases with increases either in the number of internal modes or in the degree of angular dependence. The computed periods for p modes are in fair agreement with the SCLERA observations, though it is not yet certain how they are excited.

This leaves the problem of explaining the 2 h 40 min oscillation. The observers suggest that it is indeed a fundamental radial pulsation of the Sun. If so, this measurement would upset the established theory of stellar structure and, with it, many astrophysicists. Despite the anomalous neutrino flux, it seems unlikely that the accepted theory could be so far wrong. The theorists prefer to interpret this long period oscillation as a high order gravitational mode, for the g modes have periods that increase with the number of internal modes.

Christensen-Dalsgaard and Gough also review the exciting prospects opened up by these new observations. It should soon be possible to identify the modes directly and to determine their frequencies with great precision. These frequencies can then be used to establish the properties of the solar interior and, in particular, the variation of chemical composition with radius. Such combinations of exact measurements with detailed computations are changing the nature of solar physics. This inversion procedure is similar to that used in deriving the Earth's structure from the frequencies of its normal modes (of which over 1,000 are now known). The structure of the Earth had, however, already been established by seismic observations: in the Sun, though we think we know the relevant equations, the structure has not yet been probed. Solar seismology introduces a new precision into astrophysics. □

## Solar seismology

from Nigel Weiss

THE detection of normal modes of vibration in the Sun provides the first proper check on the theory of stellar structure and evolution. By astrophysical standards, this theory is well established and precise: it predicts the properties of main sequence stars and the qualitative features of their later evolution. These successes are obtained after calibrating the theory to fit the mass, radius, luminosity and age of the Sun, all of which are known. The single other measurement that could be used to check the theory was of the solar neutrino flux. Unfortunately, this is an order of magnitude less than theory had predicted. In the last six months, however, three independent groups have announced the discovery of solar oscillations and the periods of these oscillations offer a means of probing the internal structure of the Sun.

About 10 years ago H. A. Hill set up the Santa Catalina Laboratory for Experimental Relativity by Astrometry, in Arizona, with the aim of measuring precisely the gravitational deflection of light by the Sun. To do so required an accurate technique for locating the edge of the solar disk. The SCLERA group were then able to measure the Sun's oblateness and to show that it was consistent with the observed rotation rate at its surface. In addition they discovered regular oscillatory displacements of the edge of the Sun with a period of about 48 min, together with nine higher frequencies of oscillation.

At the Crimean Astrophysical Observatory, A. B. Severny has for many years studied magnetic fields and velocities in the solar photosphere. He has also compared stellar magnetic fields

with the net field that would be measured if the Sun could not be resolved. In this issue of *Nature* (page 87), Severny, Kotov and Tsap report the result of comparing the line of sight velocity at the solar surface near the equator with that around the poles. This enables them to estimate the radial velocity and they have discovered regular oscillations, persisting for at least 7 months, with a period of  $2\text{ h }40\text{ min} \pm 0.5\text{ min}$ .

This remarkable result has been independently confirmed (page 92) by a group from the University of Birmingham. Brookes, Isaak and van der Raay were attempting to measure the gravitational redshift from the Pic-du-Midi Observatory, using a resonance scattering method. Their results, also reported in this issue, show oscillations with a period of  $2\text{ h }39\text{ min} \pm 2\text{ min}$ . The agreement is far too close to be fortuitous; the methods are so different that systematic errors have to be excluded. Thus the Sun seems also to be pulsating with a period more than three times greater than the longest period detected by the SCLERA group. (Hill's procedure was limited to periods less than about 15 h.)

In a third article in this issue (page 89), Christensen-Dalsgaard and Gough, from the University of Cambridge, attempt to identify the normal modes observed and relate them to those derived from theoretical solar models. Stellar pulsations can be classified as acoustic (p) or gravitational (g) modes. The fundamental mode of radial pulsation for a typical solar model has a period of approximately an hour, while the fundamental quadrupole mode has a period of 46 min. In general, the period of an acoustic mode

## Two more biologically active tetrapeptides

from A. J. S Davies

THE search for chemically defined mediators of interactions between mammalian cells is an arduous process. The lymphocytologists, flushed with success at their identification of T and B cells, have been trying valiantly but, aside from a long list of somewhat risible acronyms (MIF, MAF, SMAF, LIF, LAF and so on) little of repute has yet emerged. The chalone concept has been put forward but is tending to founder on the lack of support consequent upon failure of chemical characterisation of the putative medi-

ators. Thymic hormones and transfer factor are part of this twilight world of 'things' which could be useful, but which would gain more credibility if their identities were convincingly established. As we become more aware of the complexities of cell effluents and become more able to place them in biological perspective then the search and the arguments as to worth and reality will become hotter. How nice, against a background of increasing confusion, to find simple chemically defined mediators of a cell interactional process.

Goetzl and Austen (*Proc. natn. Acad. Sci.*, **72**, 4123-4127; 1975) describe in their paper two sequenced tetrapeptides derived from lung tissue which have the capacity to attract eosinophils. It has been known for some time that eosinophil chemotactic factor of anaphylaxis (ECF-A) could be released from either guinea pig or human lung slices during immediate type hypersensitivity reactions, for example contact with rag weed pollen after passive sensitisation with anti-rag weed serum containing high IgE levels. Further it was found that the material released was preformed in basophils and mast-cell-rich organs. The release was modulated by the levels of intracellular cyclic nucleotides in a similar manner to the regulation of histamine release. ECF-A itself was more effective in attracting eosinophils than neutrophils in the rather artefactual chemotactic chambers used for these quantitations.

Goetzl and Austen caused release of ECF-A from human lung tissue by appropriate means or extracted it from the same kinds of lung. The lungs were surgical specimens and one wonders idly why they were removed. The ECF-A was shown to consist of two tetrapeptides the  $\text{NH}_2$ -terminal amino acid of which was either valine or alanine. These two peptides were then synthesised as was the common tripeptide Gly-Ser-Glu. Both the extracted, released and resynthesised tetrapeptides were shown to have the same high levels of activity and to have a slightly preferential attractive effect on eosinophils compared with their effect on granulocytes. It was further shown that eosinophils which had been exposed to the synthesised peptides became incapable of migrating in response to ECF-A (neutrophils were similarly inactivated).

There are many things of interest in this work. Is the factor really as specific for eosinophils as its name indicates? Do the various lymphocytic regulators of eosinophilia operate by causing release of the factor or do they operate solely by potentiating the production of the appropriate antibody in order that an anaphylactic release

might occur? Are these tetrapeptides mediators *in vivo*? One also wonders what is the functional relationship between ECF-A and tuftsin, the phagocytosis-stimulating tetrapeptide (Nishioka, *et al.*, *Biochem. biophys. Res. Commun.*, **47**, 172-179; 1972). Tuftsin and ECF-A are dissimilar in sequence but the existence of at least three tetrapeptides which have biological activities in relation to granulocytes could indicate that many such molecules exist. □

## The IPCS—a major advance in astronomical spectroscopy

from M. S. Longair

It is now over two years since the first spectra taken with the Image Photon Counting System (IPCS) developed by Alec Boksenberg and his collaborators at University College London caused a major stir in astronomical circles. Advanced electronic and television techniques had been applied to astronomical spectroscopy in a device which counts the numbers of photons in different wavelength ranges and stores this information in a computer. Since then a steady flow of papers containing important results obtained with the system have appeared, in particular two recent papers on the quasar 3C273 and the nucleus of the nearby Seyfert galaxy NGC4151 (Boksenberg *et al.*, *Mon. Not. R. astr. Soc.*, **172**, 289 and **173**, 381 respectively). Both sets of observations were made with the Isaac Newton 98-inch telescope at the Royal Greenwich Observatory, Herstmonceux.

In normal astronomical spectroscopy, the light dispersed by a diffraction grating is focused on to a photographic plate and the information is recovered by developing the plate and measuring features directly from the plate or from some form of isodensitometer tracing. In the IPCS, the dispersed light is focused on to the photocathode of an image intensifier of very high gain. Each photon registered by the image intensifier produces a "spot" of light at the output of the tube which is continuously scanned by a television camera. By electronic processing, this "spot" of light is recognised as a single photon appearing at a single point in the dispersed spectrum. The photons are binned into 1,024 separate wavelength channels spanning the wavelength range of the grating. The television scanning technique enables the infor-

mation on each arriving photon to be transmitted to an on-line computer which stores the information continuously in core. Thus the accuracy with which the spectrum can be observed is limited by counting statistics of the photons detected. In turn this is determined by the cathode efficiency of the image intensifier which in the best modern tubes is better than 20% in the blue.

In practice, the IPCS system is operated in a dual-beam mode, with the object in one aperture and a nearby blank region of sky in the other so that the sky background and the background dark current in the image intensifier can be measured directly. It is normal practice to make two sets of observations with the object and background apertures interchanged to compensate for variations in the sensitivity in different parts of the photocathode. Subtraction of the backgrounds is then trivially performed in the computer. Once the observations are completed, the observer can display the spectrum of the object on a television monitor and plot it on large scale graph paper. Additional facilities include provisions for smoothing the spectrum, removing the sloping continuum to measure precisely the centre wavelength of spectral features and so on. The observer can come away from the telescope with his spectra calibrated and ready for analysis. The spectra shown in the papers on 3C273 and NGC4151 illustrate the effectiveness of the sky subtraction technique, the sky lines having almost completely disappeared from the spectra.

There are many practical advantages in such a system which greatly simplify the process of taking astronomical spectra. The integrated spectrum can be observed "growing" in real time as the observation proceeds since the total counts can be continuously displayed on the television monitor. This is particularly valuable when the objects being observed are too faint to be seen visually through the telescope eye-piece and off-set guiding is necessary. Also as the information acquired is directly stored in the computer, there is no possibility of "forgetting to put the plate in" or "ruining the plates". The system is designed to study faint objects and with the 200-inch telescope, for example, the spectrum of a quasar of 20 mag can be obtained in about half an hour. If the rate of arrival of photons is too great the television scanning system saturates, but since many of the most interesting objects are very faint—quasars, radio galaxies, globular clusters in external galaxies—this is not considered by most astronomers to be a disadvantage.

Since it has come into operation the system has proved very reliable and a

negligible percentage of observing time has been lost through faults in it. A measure of the high regard which astronomers have for this device is the fact that it was used continuously on the 200-inch Hale telescope for a period of over 2 months last year and over 500 spectra obtained. At present it is the most powerful system of its type in the world.

The quality of the spectra displayed in the two papers in *Monthly Notices* speak for themselves. Besides the increased speed with which such spectra can be obtained, the main advantages lie in the determination of the absolute intensities of the lines and in the ease with which broad or weak features in the spectra can be recognised. For example, in the spectrum of NGC4151, over 80 narrow lines can be identified and absolute intensities are quoted for all of them. This much improved data base provides a new challenge to theorists for the construction of models of the line-emitting regions in complete nuclei. Perhaps more striking is the presence of very broad wings on the Balmer lines, the lines of He II and of Fe II. These are all permitted transitions and are much broader than the forbidden lines. The fact that no broad forbidden Fe II emission is observed indicates that the broad spectral features arise in regions where the particle density is greater than  $10^7 \text{ cm}^{-3}$ . This situation is very similar to that observed in 3C273 where the forbidden lines are either very weak or absent. In this respect 3C273 differs from most other quasars.

These papers represent the tip of the iceberg—hundreds more spectra await analysis in many different fields of astrophysics. Systems such as the IPCS will shortly be standard equipment on all the large optical telescopes; for example, Boksenberg and his colleagues are at present building a new version of the IPCS for use on the 4-m Anglo-Australian telescope. Thanks to the development of these devices, many very large scale projects which would have seemed quite impracticable 10 years ago are now within the capabilities of the new generation of telescopes. □

## Madagascar issue settled

from Peter J. Smith

THE geographical position of Madagascar before the breakup of Gondwanaland has been a source of controversy for well over a decade. Before Wegenerian drift began, did this continental fragment lie to the north or

south of its present location? Or has it always been at its present latitude, with only a small eastward drift to take it away from the African mainland and create the Mozambique Channel? The confusion now seems to be over, as palaeomagnetism has provided the definitive answer (Embleton and McElhinny, *Earth planet Sci. Lett.*, **27**, 329, 1975).

The first person to say anything about the ancient position of Madagascar was Wegener himself who placed the island in the large coastal embayment of Mozambique, or about 4° south of its present position. Intuitively (which is simply to say that there is some worth in the Baconian rule of "conformable instances"), this is the obvious place to put it, although there are also some respectable geological arguments for this view as Flores (*Trans. geol. soc. S. Africa*, **73**, 1; 1970) has shown. On the basis of aeromagnetic profiles across the Mozambique Channel, Green (*Nature phys. Sci.*, **236**, 19; 1972) also supported a fit against Mozambique, in which he was followed, on other grounds, by Kent (*Nature*, **238**, 147; 1972).

On the other hand, Darracott (*Earth Planet. Sci. Lett.*, **24**, 282; 1974), taking account of the thin continental-type crust in the Mozambique Channel, concluded that Madagascar has always been at its present latitude but has drifted slightly eastwards. This was a slight variant of an earlier proposal from Flower and Strong (*Earth planet Sci. Lett.*, **7**, 47; 1969) that the island has remained stationary, although Wright and McCurry (*Earth planet. Sci. Lett.*, **8**, 67; 1970) felt that the evidence cited by Flower and Strong could not be taken to exclude eastward drift, arguing instead that Madagascar once lay against Mozambique.

The third and, on the face of it, more radical proposal is that Madagascar has moved about 15° southwards and slightly eastwards, in which case it would have originated against Kenya and Tanzania. This view was first put forward by Du Toit (*Our Wandering Continents*, Oliver and Boyd, Edinburgh, 1937) largely on the basis of matching lithologic units and later supported by Smith (A. G.) and Hallam (*Nature*, **225**, 139; 1970) on the basis of a computer fit of the 500-fathom contour. After carrying out a geophysical survey in the Mozambique Channel, Heirtzler and Burroughs (*Science*, **174**, 488; 1971) also concluded that Madagascar has drifted southwards.

Among the mass of conflicting geological and geophysical evidence, palaeomagnetic data is conspicuous by its absence. It is easy to be wise after the event, but an obvious way of deciding between the three hypotheses

would be to obtain a palaeomagnetic direction for rocks laid down on Madagascar before Gondwanaland split and compare it with African mainland directions for the same epoch. It is true that over a decade ago Nairn (*Overseas Geol. Min. Resour.*, **9**, 302; 1964) obtained a palaeomagnetic direction from the Karroo sediments of Madagascar, but no magnetic cleaning techniques were used and at that time there was no suitable African data for comparison.

Using modern methods, Embleton and McElhinny have now obtained a good palaeomagnetic pole position from Triassic-Jurassic sediments on Madagascar and have compared it, first, with the Triassic-Jurassic African pole and, second, with the African pole for the whole of the Mesozoic (possible because Africa has apparently remained fixed in position during this period). Irrespective of how the comparison is carried out, there is no significant difference between the Madagascan and African poles only if Madagascar was north of its present position during the Triassic-Jurassic. In other words, according to palaeomagnetic evidence there is little doubt that before the onset of Wegenerian drift Madagascar lay off the east coast of Africa adjacent to Kenya and Tanzania.

Having made this central point, Embleton and McElhinny go on to cite the geological and faunal observations in its favour. This evidence is convincing too, although no doubt some puzzles still remain. The fact is, however, that the grounds of argument have now shifted. Any geological 'anomalies' must now be reconciled with Madagascar's northern origin; they can no longer be regarded as convincing evidence against it. □

## Immunoglobulins: constant sequences in the variable region

from Pamela Hamlyn

ANTIBODIES—the vast number of protein molecules which react specifically with foreign substances to trigger the immune response—are complex molecules all very similar in design. Each has two heavy (H) and two light (L) chains. Both H and L chains contain a constant (C) and a variable (V) region with regard to amino acid composition. Analysis of related L chains has shown that different amino terminal regions are associated with the same C region and has led to the suggestion that, unlike all other polypeptides, two genes are needed to code for one polypeptide chain. The number of C region genes

seems to be small but there is controversy over the number of V region genes. These genes code for the enormous number of polypeptide chains which confer specificity on the antibody molecules.

Theories to account for the diversity of the V region genes fall into two main categories. Either they suggest that there is a very large number of genes in the germ line encoding the many V regions, or that the number of genes in the germ line is small but it is amplified by somatic processes such as mutation, recombination or excision and repair with error of the DNA. Despite very many attempts in the years following the publication of these proposals no experimental data has been obtained which clearly establishes one theory over the other. Recent information on the V region of L and H chains indicates that variability is localised in interspersed hypervariable regions. The remainder of the V region (framework segments) show a remarkable preservation of amino acid sequences among related chains.

Capra and Kindt have described a model to account for these observations (*Immunogenetics*, 1, 417; 1975). They propose that the interaction of at least three genes is required to form each immunoglobulin polypeptide chain, the relatively invariant portion of the V region being encoded by a limited number of germ line genes while the hypervariable genes would be coded for by a larger number of genes, perhaps 50–100. By some integration mechanism the hypervariable genes would interact with the basic subgroup genes to form the completed variable region which would then, by a further integration, link to the constant region to form the completed gene for the whole polypeptide chain. This model helps to reconcile some of the conflicting evidence used in support of the alternative theories.

Some recent experiments of Friedenson, Tung and Nisenoff (*Proc. natn. Acad. Sci. U.S.A.*, 72, 3676; 1975) could be used to lend support to Capra and Kindt's model. They isolated antibodies of the same specificity from nine individual mice immunised with the same antigen and used the H chain for amino acid sequence analysis of the first thirty or so N terminal amino acids. They found that the amino acid sequences were all identical. Previous studies of this framework region had investigated amino acid sequences in antibodies pooled from several mice so that occasional amino acid substitutions (arising from somatic mutations) would have been difficult to detect. These results therefore strongly imply that somatic mutations do not occur in the

first framework segment and the authors suggest that this may be extrapolated to apply to framework regions in general. Sequence data on the remainder of the variable region will of course be necessary to see if this extrapolation is justified, and to see how the sequences in the hypervariable regions are related in different individuals. □

## So the coelacanth does bear live young

from a Correspondent

A SHORT paper published in *Science* (190, 1105; 1975) by C. Lavett Smith, Bobb Schaefer, and James W. Atz of the American Museum of Natural History, New York, and Charles S. Rand of the Department of Biology, Long Island University, announces the discovery of five advanced young within the body of a preserved female coelacanth, *Latimeria chalumnae*. Their discovery finally settles a long period of uncertainty as to whether *Latimeria* lays eggs or bears live young.

Since its discovery off South Africa in 1938 the coelacanth has been slow to yield its secrets. It was not until 1952, following wide publicity by the late J. L. B. Smith (who described the first specimen), that a second specimen was captured, this time off the Comoro Islands. This revealed the true geographical range of the species to be this French possession in the western Indian Ocean, and since that date some 80 specimens have been captured—all by native fishermen—despite two expensive multinational expeditions to the Comoros. Most of these specimens have been retained in France, one of the exceptions, however, was the female 1.6 m in length and weighing 65 kg at capture in 1962 that is now in the American Museum of Natural History.

*Coelacanth young with yolk sac*

Despite this apparent wealth of material the key question as to whether these fish lay eggs or give birth to live young remained unanswered. Millot and Anthony (*C. r. Acad. Sci. Paris*, 251, 442; 1960) described a female with eggs in the right oviduct (the left oviduct is non-functional) which appeared to confirm oviparity, as had been suggested by the apparent absence of any copulatory organ in the male, and by their earlier dissections of the urogenital systems and orifices of both sexes. Then a female was found with 19 large eggs in the oviduct, these apparently fully-developed eggs being 8.5–9.0 cm in diameter and weighing around 318 g. This appeared to clinch the matter, and Millot and Anthony's view was held by some as confirmed.

There were heretics, however. R. W. Griffith and K. S. Thomson (*Nature*, 242, 617; 1973) pointed out that osmoregulatory demands would be too great to allow a shell-less egg of this size to develop in seawater. In addition, it seemed hard to believe that a fish of this size, with such a low fecundity could possibly have survived by simply laying tennis-ball sized eggs, even if they were hidden in a rock crevice or a nest. While the adult might have protected them from large predators, they would have been open to attack from the numerous crustacean inhabitants (particularly amphipods) of such a habitat. It would have seemed logical to assume that either *Latimeria* mouth-brooded its developing eggs (as do other marine fish which produce few large eggs), or more likely that the eggs developed internally.

Despite this, so deeply rooted was the notion that *Latimeria* was oviparous, that a recent authority (P. H. Greenwood, *A History of Fishes*, third ed., London, 1975) could write, "It must be assumed therefore that the fertilised eggs are physically unprotected; perhaps there is some form of parental care?"

The recent discovery by C. Lavett Smith and his co-workers thus puts an end to an era of muddled deduction. They report that five advanced young of lengths between 301 and 327 mm, and with moderately large yolk sacs (diameter 80–129 mm) were found in the specimen in New York. The young lie free in the oviduct and *Latimeria* is thus definitely ovoviviparous. Apart from their rather larger eyes and a more rounded head profile they resemble the adult closely. Fins and scales are well developed although they lack the fine teeth on the scales of the adult. Smith *et al.* point out that the female was captured in January (the same month in which females with ovulated eggs were taken) and they suggest from this that gestation may require more than a year.

Interestingly, the recent discovery that coelacanths are live-bearers was anticipated from the fossil record by nearly fifty years. D. M. S. Watson (*Proc. zool. Soc., London*, 453; 1927) reported the discovery of two small specimens of *Holophagus* (as *Undina*) within the body cavity of a larger specimen of this Jurassic fossil. It is pleasant that after this lapse of time Watson's observation on the fossil coelacanth has been confirmed by examination of the only living survivor of the group. □

## The meiotic process

from a Correspondent

A Royal Society meeting for discussion on The Meiotic Process was held in London on December 10 and 11, 1975.

THE meeting explored fully the biological roles of meiosis: the halving of chromosome number in the formation of gametes and the synapsis and subsequent genetic recombination between homologous chromosomes. Opening the meeting, C. D. Darlington (University of Oxford) set the tone by pointing out that the chromosomes do not follow the laws of heredity, they make the laws. Almost every subsequent paper was concerned with one or other aspect of the movement, crossing over or disjunction of chromosomes in the two cell divisions which make up meiosis. The dominant theme was the study by electron microscopy of the synaptonemal complex (SC), an organelle of remarkably uniform dimensions and appearance in a wide range of eukaryotes, which mediates the pairing of homologues at the pachytene stage of meiosis.

Reconstructions of pachytene nuclei from serial sections show that the SCs extend along the whole length of the paired chromosomes (bivalents) and are usually attached at either end to the nuclear membrane. One of the major problems is to explain why bivalents do not become interlocked. S. W. Rasmussen (Carlsberg Laboratory, Copenhagen) showed that at an early stage in pairing in the silk worm, *Bombyx*, interlocking can in fact occur, but is in some way eliminated at a later stage. In this organism there is no crossing over or chiasmata formation in females and a progressive modification of the structure of the SC ensures that the chromosomes are held together until metaphase. D. von Wettstein (Carlsberg Laboratory, Copenhagen) showed that in normal

meiosis, where crossing over occurs, the SC is discarded after pachytene and can accumulate as polycomplex material dissociated from the chromosomes. A small part of the SC remains associated with the homologues at diplotene, probably at the points of crossing over. The importance of the recent discovery of nodules or nodes was emphasised by D. L. Lindsley (University of California, San Diego). These are discrete, densely stained bodies of unknown composition lying within or just outside the SC. Carpenter has obtained very suggestive evidence from *Drosophila* that the nodules in some way mediate or are associated with cross overs. Although a wealth of morphological information is available about the SC, so far almost no chemical work has been done. The major component is protein, probably with associated RNA, but it is completely unknown whether DNA enters the SC very occasionally at sites of crossing over, or at many sites, only a few of which generate cross overs.

Other approaches to the problem of pairing have been made with wheat and other cereals by R. Riley, R. B. Flavell and G. A. Dover (Plant Breeding Institute and Department of Genetics, Cambridge). In a wide range of cytological and physiological studies, the importance of the 5B and 5D chromosomes in controlling homologous and homoeologous pairing has been established. It has been shown by temperature shift experiments and by colchicine treatment that events occur before the premeiotic S phase which are essential for normal chromosome pairing. The favoured hypothesis is that homologous chromosomes are pre-aligned at this stage and that a colchicine-sensitive fibrillar protein is involved. M. P. Maguire (University of Texas, Austin) also presented visible evidence for pre-aligned chromosomes in maize. M. D. Bennett (Plant Breeding Institute, Cambridge) showed that there is a linear relationship between DNA content and the duration of meiosis, which is independent of chromosome number. However, increases in ploidy within a species broke this rule and decreased the time of meiosis.

The importance of mutants in probing meiosis was best shown by the detailed studies of D. L. Lindsley and L. Sandler with *Drosophila*. A very large number of mutants are known which may specifically affect synapsis, crossing over or disjunction at the first or second division. Some are being exploited in further studies of the cross over 'nodule'. Many meiotic mutants also exist in yeast, and P. B. Moens (York University, Ontario) described two which are blocked in premeiotic DNA synthesis, but which nevertheless continue to proceed through meiosis

and form recombinants. One of the highlights of the meeting was the film by B. Nicklas (Duke University, North Carolina). He showed that by physically reorienting bivalents of grasshopper meiotic cells, the direction of movement of the chromosomes of metaphase I was determined by the direction in which the kinetochore (centromere) is pointing. Using the method of Telzer *et al.*, he has demonstrated *in vitro* that this may be related to the spontaneous association of tubulin with the kinetochores.

R. Holliday (National Institute for Medical Research, Mill Hill) discussed the likely mechanism of reciprocal and non-reciprocal recombination at the molecular level in relation to the processes of pairing and the formation of chiasmata. Cross overs between naked DNA molecules must be stabilised to form the chiasmata which hold the bivalents together, whereas non-reciprocal events may be transient. In an attempt to explain the ubiquitous phenomenon of interference between cross overs, he suggested that the SC may contain a limiting amount of a DNA-binding protein which is essential for their stabilisation. A major problem in our understanding of meiosis is the lack of biochemical information. The only systematic study has been made by H. Stern and Y. Hotta (University of California, San Diego) using *Lilium* and *Trillium*. In a review of the advances that have been made, Stern described the properties of the minor fractions of DNA synthesised at zygotene, which may be involved in pairing, and in pachytene, which may be due to repair synthesis during recombination. The latter is absent in the achiasmatic hybrid Black Beauty. Proteins which are synthesised at meiotic prophase and may play an essential role in recombination are a DNA-binding lipoprotein and an endonuclease.

Finally, D. Lewis (University College London) presented in one of the discussion periods an intriguing, although somewhat unrepeatable experiment. He described how in late Summer during the war, a V-1 flying bomb exploded at the John Innes Horticultural Institute, resulting two weeks later in out of season induction of meiosis and blossom in apple and particularly plum trees. It soon became apparent that the denudation of leaves was the main effect of the explosion. The result of this experiment, previously kept secret, indicated that the maturation of meocytes may be under the control of inhibitors, produced in this case by the leaves of the trees. This was certainly one of the most exciting experiments presented, and if published, the Materials and Methods should provide particularly interesting reading. □

## Scientific plans for deep sea drilling

C. A. Williams\*

*The Deep Sea Drilling Project is about to launch phase IV of its drilling operations, known as the International Phase of Ocean Drilling (IPOD). Plans for the first year of IPOD are well under way and a preliminary drilling schedule for the first four years has been drawn up. At this stage it is appropriate to inform the scientific community in general of these plans and to invite comment and suggestions. As in the past the scientific planning is carried out by the Joint Oceanographic Institutions for Deep Earth Sampling (JOIDES). This organisation, international from the outset, will through its various panels continue to provide scientific advice to DSDP for the IPOD programme as it has to the previous phases of drilling.*

THE drilling project dates from the early 1960s when four major oceanographic institutions in the USA, Lamont-Doherty Geological Observatory of Columbia University, the Rosenstiel School of Marine and Atmospheric Science of the University of Miami, Scripps Institution of Oceanography of the University of California in San Diego, and Woods Hole Oceanographic Institution, formed JOIDES. An initial and successful drilling programme was carried out, under contract from the NSF to Lamont-Doherty, during the summer of 1965 on the Blake Plateau off Florida using the vessel Cardrill I. NSF next awarded a contract to the University of California for an 18-month programme, the Deep Sea Drilling Project (DSDP), in the Atlantic and Pacific Oceans. Phase I of this project, using the drilling vessel Glomar Challenger, began in August 1968. Since then the project has successfully continued through phases I-III, having completed phase III at the end of leg 44 in summer 1975. During this period approximately 400 holes have been drilled and ocean drilling pioneered in all major oceans.

The success of this project springs largely from the parallel programme of research and development into the technical aspects of drilling that has coexisted with the drilling operations, and which has provided both increased sophistication of methods and production in terms of material retrieved. Deeper holes can now be drilled with new improved drill bits, though perhaps the greatest advance is due to the development of the re-entry system, enabling a worn drill bit to be replaced and the hole re-entered for drilling to be continued. The next technical milestone will be the construction of a blow-out prevention system, which will open the way to a range of ocean margin sites presently inaccessible due to the possible encounter of high pressure fluids and gases within the sediments.

### New emphasis during IPOD

IPOD will concentrate on drilling below the sedimentary cover of the ocean floors and intends to penetrate deeper into the ocean floor than ever before. There will also be

a greater concentration on fewer but deeper holes and an entire 56-d leg, or possibly longer, of Glomar Challenger's time will be spent on a single hole, penetrating to a depth of up to 2 km into the sea floor, IPOD I, lasting 4 yr, will continue to use the Glomar Challenger, but during IPOD II, when deep holes into marginal basins and deep-sea trenches are planned, it is anticipated that another drilling vessel, or platform, will be used.

Coupled with this re-emphasis, are changes in the organisation of JOIDES. After the initiation of JOIDES by the four US member institutions, the University of Washington became associated with the drilling project in 1968. During 1974-75 not only did the US membership increase to nine institutions with the addition of the Hawaii Institute of Geophysics, University of Rhode Island, Oregon State University and Texas A & M University, but it is now a formally recognised international organisation with member scientific institutions in the USSR, West Germany, France, Japan and the UK. Financial support for the programme continues to be mainly from the NSF, but with additional contributions from the member nations of IPOD/JOIDES.

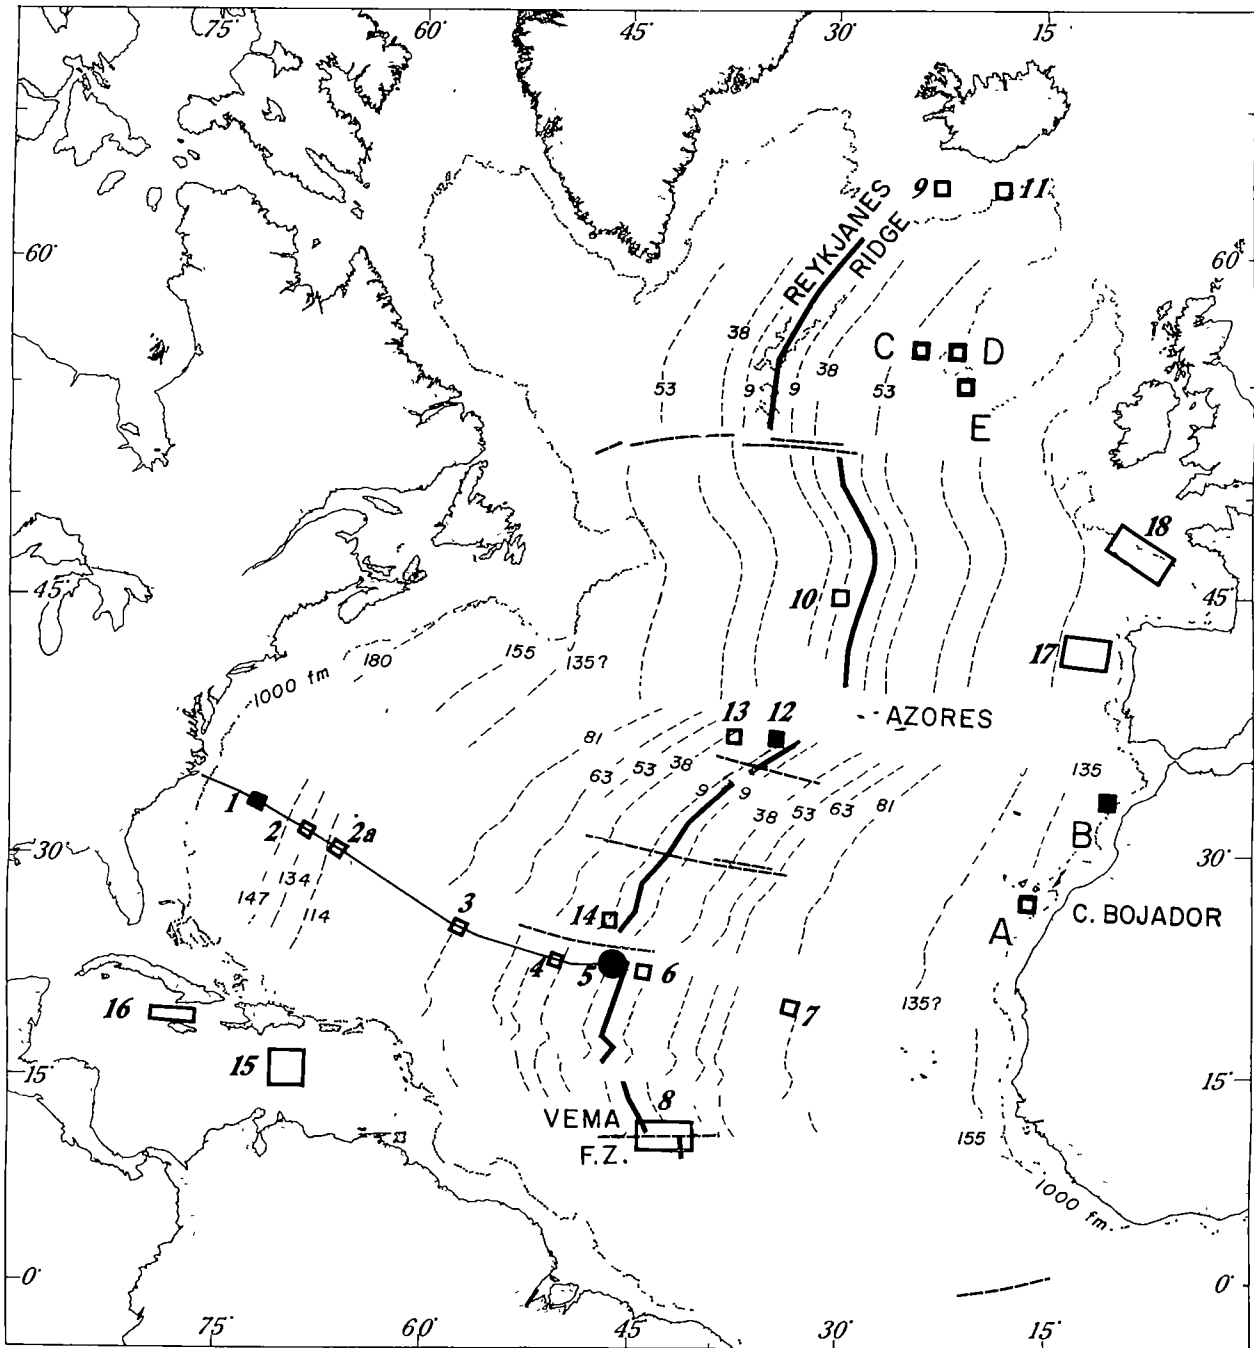

The scientific approach of IPOD differs fundamentally from the previous drilling philosophies in that it is problem, rather than geographically, oriented. JOIDES advisory panels now include four problem panels concerned with the ocean crust, ocean margins (active and passive) and ocean palaeoenvironment.

Since effort will be concentrated on fewer sites, it is essential that the optimum locations be chosen; thus site surveying will also have a considerably more important role than it has during phases I-III. An IPOD Site Survey Management group, situated at Lamont-Doherty Geological Observatory, is designated to coordinate the survey programme and handle subcontracts for IPOD site surveys carried out by US institutions. The input of non-US data into this group remains on a voluntary basis and scientists who have relevant data are encouraged to submit this information for inclusion into the site data package for the chief scientists of that leg.

### Atlantic drilling plans

Five of the first seven drilling legs to be spent in the North Atlantic will be devoted to the study of the oceanic crust. One of the main objectives is to establish a model for the

\* Address: Lamont-Doherty Geological Observatory, Columbia University, Palisades, New York 10964.

**Fig. 1** Proposed IPOD Atlantic drilling sites. Open squares denote single bit sites, filled squares deep sites and filled circles very deep sites. The ages of the sea floor (Myr) are shown along magnetic lineations. The larger boxes indicate the region of several sites not yet precisely determined.

physical, geochemical, petrological, magnetic, thermal and other properties of the oceanic basement and to determine their range of variations, both with time (distance from the mid-ocean ridge crest) and location (along the length of the ridge crest).

The spatial and temporal problem will be tackled by way of two transects. An east-west transect along a 'flow' line (sites 1-7 in Fig. 1) will sample crust that has originated from the same spot on the ridge crest as determined from magnetic anomalies; in this way the variation with age away from the ridge crest will be investigated. The second transect, parallel to the ridge crest, will mainly be on magnetic anomaly 5 West (9-Myr-old sea floor) between latitudes 63°N on the Reykjanes Ridge and 12°N on the Vema Fracture Zone (sites 8-14). Local crustal variability will be investigated by means of shallow trial holes close to each site.

A test for the symmetry in crustal properties on either side of the Mid-Atlantic Ridge will be made by a comparison of samples at sites 3 and 5 with those from sites 7 and 6.

Sites are classified as being either single bit, that is, drilled to the limit of wear of one drill bit, which, depending on the hardness of the rocks encountered, could give a penetration of up to 500 m. Single re-entry sites which will penetrate deeper than 500 m and involve 6-10 d of drilling, and very deep sites involving multiple re-entry, penetration down to 2 km, and take 1-1½ legs of drilling. Atlantic site 5 (Fig. 1) is regarded as a prime site for a very deep hole and will be drilled early in the programme.

The sediments at all holes will be continuously cored and it is hoped that a logging programme can be implemented for some of the holes. Site 10 will be near 45°N. Site 14 is in the trans-Atlantic geotraverse corridor near 26°N; both

are areas well investigated by previous work and requiring little or no additional site surveying. Five holes are planned at Site 8 in the Vema Fracture Zone area. These will be to investigate the nature of the fracture zone and will also extend the longitudinal transect southwards to 12°N.

The original intent of the longitudinal transect was to sample the crust at shallow sites, more or less evenly spaced along the length of the Mid-Atlantic Ridge on magnetic anomaly lineation 5 west. Site 9 will be on magnetic anomaly 5 east and site 11 on the same 'flow' line but on older oceanic crust at anomaly 13 (38 Myr), to investigate the Iceland geochemical anomaly. This represents a trend away from the initial purist approach of avoiding as far as possible any known geochemical anomaly. The change in policy represents both the scientist's inherent propensity to investigate anomalies, or recognition that simple situations only exist where investigation has not yet proved otherwise. As our knowledge of the ocean floor grows, it may become apparent that it is impossible to avoid anomalies. Site 13 will be on anomaly 13 west, along the corresponding flow line west of the FAMOUS area, where, as a result of the very considerable Franco-American effort to study a small area of the Mid-Atlantic ridge crest in great detail, perhaps more is known of the ocean floor than in any other area. Site 12, which will be a deep site near DSDP site 334, and Site 13 will thus form a separate east-west mini-transect in the same way as sites 9 and 11.

Of the first few legs to be spent in the North Atlantic, two of these will concern themselves with the problems of the continental margins. At this stage, four specific areas have been designated: Off north-west Africa, sites A and B, Galicia Bank (area 17), the northern margin of the Bay of Biscay (area 18) and Rockall Bank sites C, D and E (Fig. 1). The first of these sites to be drilled will be site A off Cape Bojador, and a re-entry site in the Morocco Basin. Here it is hoped to sample pre-Oxfordian sediments in the North Atlantic for the first time. Both these holes will also investigate the nature of the sediments relating to the history of this margin during the opening of the Atlantic Ocean approximately 180 Myr ago.

Three sites will be located on Galicia Bank, the submerged continental block which enigmatically does not fit into the reconstruction of the Atlantic continents. The age of the oldest sediments overlying the oceanic crust will be sampled to the west of the bank, and then at a site on one of the faulted blocks on the south or western slope of the Bank, information will be sought on the age and processes involved during the initial rifting apart of the continents. A site on the top of the carbonate platform will investigate the stratigraphy and subsidence history of the platform itself.

Another designated area of interest is the northern continental margin of Biscay, where at three single-bit sites the history of subsidence and sedimentation of this region will be investigated in the light of the history of opening of the Atlantic and Bay of Biscay. Three sites (C, D and E in Fig. 1) are also proposed near the south-west end of Rockall Plateau where the objective is to investigate the history of subsidence of the margin relative to the three different phases of continental separation which have occurred peripherally to Rockall Bank, during the Lower Cretaceous(?), at 80 and 60 Myr.

Additionally, a leg may be devoted to the Norwegian Sea where both crustal and margin problems will be investigated. This programme is still in its initial planning stages, and the proposals for this area will shortly be reviewed by the JOIDES ocean crust and safety panels.

## Palaeoenvironmental aims

The Ocean Palaeoenvironment Panel is interested, through the study of faunas and sediments, in developing a model

for the opening and subsequent evolutionary history of the ocean basin from the point of view of their palaeoclimate, palaeocurrents and so on. The panel also has more specific aims, including a study of the early history specifically of the Atlantic, and to investigate the Cretaceous-Palaeogene boundary as an example of a palaeoecological crisis. Many of their other interests in global ocean circulation, the evolution of plankton communities through time, and so on, require a more extensive global coverage of data than do those of the other panels, and the Palaeoenvironment Panel would like to drill in the Indian Ocean, Antarctic and the South Atlantic as well as in the North Atlantic and North Pacific. There are, however, already more proposals than can be fitted into the programme and even with the recent extension of IPOD I from a 3-yr into a 4-yr programme, it will not be possible to drill in the Indian Ocean or the Antarctic during IPOD I. Two palaeoenvironment legs are planned, however, in the South Atlantic where sections across the Angola and Cape Basins will further investigate the effect of the Walvis Ridge on the early history of sedimentation in the Atlantic.

The development of early plankton communities can be investigated in the northern Pacific, where a hemispherical ocean with an uncomplicated gyral current system is required. Eighteen holes are proposed across the northern Pacific for this programme. The Cretaceous-Palaeogene boundary can be investigated near the Sierra Leone Rise in the Atlantic and also at sites near Rockall Bank, in the Caribbean and in the NW and equatorial Pacific, which will tie in with the other parts of the programme. Volcanic episodicity can also be studied from ash layers in the sediments at sites in the Sea of Okhotsk, the Japan Sea, off Central Chile and also at ocean crust sites near Hawaii and Iceland.

## Pacific drilling plans

Drilling plans for the Pacific are still in outline (see Fig. 2), but the programme will be planned in many respects to parallel the Atlantic work, to compare the slow spreading (half rate of 1–2 cm yr<sup>-1</sup>) Atlantic with the faster spreading (6–10 cm yr<sup>-1</sup>) Pacific. It is not feasible to follow a single flow line across the Pacific as in the Atlantic, and hence the major traverses are split between several flow lines. Two, possibly alternative sites (1 and 3 in Fig. 2) have been chosen to sample very young ocean floor. These candidate sites in the Gulf of California and on the Juan de Fuca Ridge, are both where sufficient sediments to support, or 'spud in', the drill bit occur at the ridge crest. Such sites should provide information on hydrothermal circulation within the crest which may only occur near the ridge crest, on thermal gradients and should also provide unweathered samples for geochemical analysis. The presence of sediments at the ridge crest probably causes an intermixing of lava and sediment and implies that the basement here could be anomalous; however, the value of obtaining very young samples is considered to outweigh this factor.

The fastest Pacific seafloor spreading area, at 20°S, is remote, has a confused magnetic pattern, a thin sediment cover and was rejected in favour of the Siqueiros Fracture Zone at approximately 8°N on the eastern north Pacific (site 4). This relatively fast-spreading transect is planned with sites on 2- and 5-Myr-old crust in sediment ponds existing within 10–20 km of the ridge crest and where seismic refraction data indicate a low velocity zone (possibly the magma chamber?) centred beneath the ridge crest. The spreading rate here was approximately 5 cm yr<sup>-1</sup> over the past 10 Myr, three times that of the Atlantic and adequate to compare the evolution of fast and slow spreading ridges.

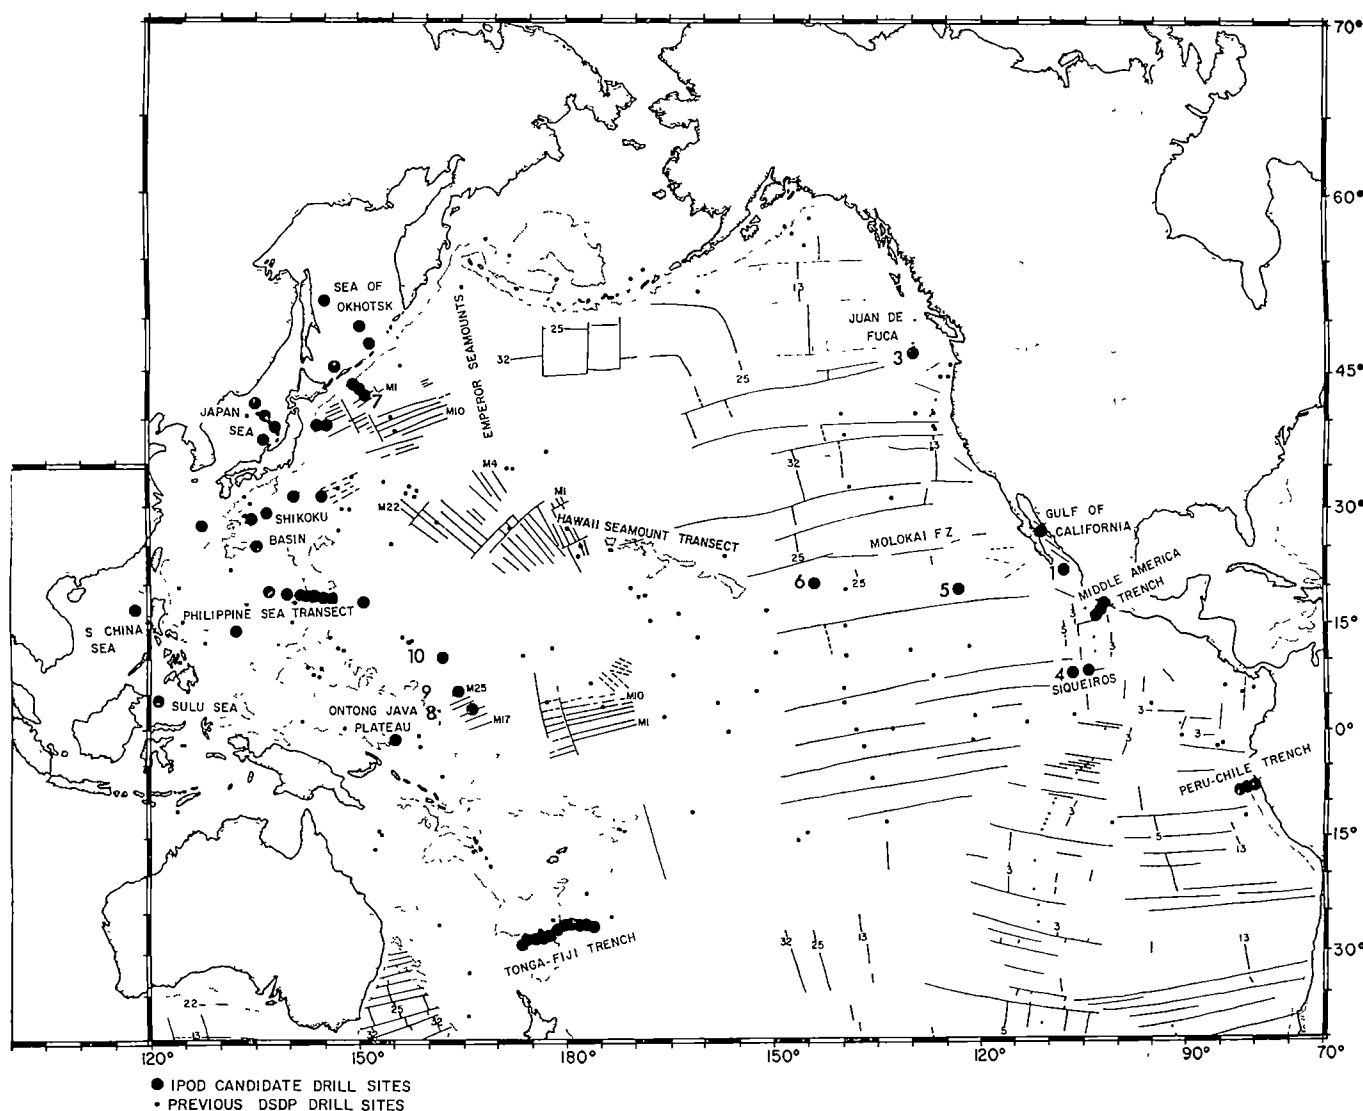

Fig. 2 Proposed IPOD Pacific drill sites. The larger circles denote the proposed IPOD sites and the smaller circles show previously drilled DSDP sites. The multi-site traverses are indicated diagrammatically since the scale of the map does not allow otherwise.

This will be one of the high priority areas for very deep penetration.

Pacific sites 5 and 6 will be shallow holes on anomalies 10 (33 Myr) and 32 (76 Myr) respectively and lie on a flow line south of the Molokai fracture zone which will tie in with the Gulf of California sites.

The oldest known Pacific sea floor and the Jurassic quiet magnetic zone will be sampled at sites 7–10 in the western Pacific. Site 7 will lie on magnetic anomaly M1 (116-Myr-old sea floor) south of the Kurile trench and will date this important magnetic anomaly and also tie in with a traverse from the Sea of Okhotsk across the Kurile trench chosen by the Active Margin Panel. Traverses across the Sea of Okhotsk, the Shikoku Basin and south Philippine Sea are designed to investigate the formation of back-arc and marginal basins. The Philippine traverse comprises thirteen proposed sites with the intention of sampling the floor of the South China Sea, the W. Philippine Sea, the Palau-Kyushu Ridge, the east and west Parece-Vela Basins, the Mariana Islands, trench gap and trench. The results from these sites may allow for clarification between the two current conflicting hypotheses for the origin of the floors of marginal basin areas; that they are areas of entrapped old Pacific sea floor, or alternatively crust formed by sea-floor spreading within the marginal basins themselves.

A transect across the Japan Sea is planned with a series of up to 8 holes to investigate the nature of the crust in that area. All but two of these, and two of the South Philippine transect sites, demand penetration beyond the present capabilities of Glomar Challenger with a 6.7-km long drill string and will be candidate sites for the second phase of IPOD drilling when an 11.0-km drill string is planned. Other active margin traverses are also planned across the Tonga-Fiji trench, the Middle America Trench and the Peru-Chile trench. In due course these will be categorised into priority and contingency sites as the Pacific drilling plan evolves.

The IPOD I programme is scheduled to spend the first eight legs in the Atlantic and Caribbean, the following 12 legs in the Pacific and will return at the end of IPOD I for five final legs in the Atlantic. Clearly the candidate drill sites are already too numerous for all of them to be drilled and the task of the JOIDES advisory panels will be to pare down this number into a workable drilling plan with both established priority and contingency sites.

The JOIDES organisation is keen to hear from the scientific community at large and suggestions are welcome as to precise drilling locations, scientific staffing of the Glomar Challenger for specific legs, and the organisation and allocation of effort with respect to shore-based study of core material, together with relevant existing site survey data.

## Observations of solar pulsations

A. B. Severny, V. A. Kotov & T. T. Tsap

Crimean Astrophysical Observatory, p/o Nauchny, Crimea, 334413 USSR

*We have modified our solar magnetograph to measure velocities at the solar surface, rather than magnetic fields. Using this apparatus, we have observed fluctuations of period 2 h 40 min, which are remarkably stable. The interpretation of this phenomenon seems to cause much theoretical difficulty.*

We have reported previously<sup>1,2</sup> on the successful measurement of the Sun's magnetic field using a solar magnetograph and the Crimean Solar Tower Telescope. The magnetograph consists of an electro-optical modulator to pick out the circularly polarised Zeeman components of magnetically sensitive lines, a grating and photomultipliers set on the wings of the lines. We thus achieve sensitivity, but, with the aid of an automatic Doppler compensator, avoid the perturbations of varying relative velocities between the Earth and Sun, turbulence in the atmosphere and apparatus noise. By the use of some additional apparatus we have now investigated periodic fluctuations in the Sun's surface.

### Method and apparatus

To avoid unnecessary complications, we work with a magnetically insensitive line ( $\lambda = 5,123.7 \text{ \AA}$ ). A circular polariser was placed between the telescope and the entrance slit of the spectrograph, of such a diameter to polarise light from the central portion of the Sun only. Light from the solar rim will always reach the photomultipliers (it is initially unpolarised), but light from the central disk will get through only when the magnetograph polariser (modulated at 760 Hz) is set for it. The difference between the outputs of the two photomultipliers provides the magnetograph signal, and the different signals for the two polarisations indicates whether or not light from the centre is shifted relative to that from the rim. The Doppler shift can be converted into a line-of-sight velocity.

To avoid effects arising from the great rotational velocity of the equatorial parts of the Sun, we looked at light from a pole-pole strip across the Sun only. We calibrated the instrument with a line of known intensity and wavelength to relate a known wavelength shift to the measured signal. The interpretation of a positive experimental signal depends on the geometry of the apparatus (the ratio of the area of the polar image to that of the central image) and the mean relative emissivities of the polar regions and central ones.

With our particular geometry, we have derived the following formula for the experimental signal  $\delta_{||}$  in terms of the wavelength shift  $\Delta\lambda_v$ , assuming a triangular line profile

$$\frac{\delta_{||}}{\delta_{||}(O)} = \frac{1}{2+\beta} \frac{\Delta\lambda_v}{\Delta\lambda_c} \quad (1)$$

Here  $\Delta\lambda_c$  is the wavelength shift we produced artificially for the

calibration signal  $\delta_{||}(O)$ , with the aid of the plane-parallel glass plate of the velocity compensator (which is 'off' for calibrations, and 'on' for recording  $\Delta\lambda_v$ ), and  $\beta$  is the ratio of the intensity at the central part of the solar image to that at the rim,  $\beta = I_c/I_r \approx \frac{1}{2}$  in our case (intensities measured by photomultipliers). The calibration is made for a standard shift  $\Delta\lambda_c = \pm 0.031 \text{ \AA}$  of the  $5,123.7 \text{ \AA}$  line, which corresponds to velocity of  $\pm 1,815 \text{ m s}^{-1}$ , so that  $\delta_{||}$  equals  $\delta_{||}(O)$  when  $\Delta\lambda_v = 2.34 \times \Delta\lambda_c$ —for a speed of  $4,238 \text{ m s}^{-1}$ .

### Accuracy of experiment

The accuracy of the method is limited by turbulence in the spectrograph and electronic noise, and can be determined from the accuracy of magnetic field measurements<sup>2</sup>: where mean field strengths of 1 gauss were measured, corresponding to  $\approx 2.2 \text{ m s}^{-1}$ . By increasing the data accumulation time to 15 min, we can achieve  $\approx 1.0 \text{ m s}^{-1}$ , corresponding to a Doppler shift  $\Delta\lambda_v \approx 10^{-5} \text{ \AA}$ .

A special auxiliary guiding system ensured angular accuracy of  $\pm 0.1'' \times 0.2''$  in positioning the beams. There were also effects varying regularly during the whole day connected with slowly changing imbalances in both the electronic channels of the magnetograph, or of photoguiding system, but this slow run of the signal was easily eliminated (especially when we compared the records of two independent magnetographs in our double-channel magnetographic system<sup>3</sup>). In all, 122 h of data (from 21 d) were obtained (August–October 1974 and March 1975).

### Analysis

Analysis showed at once the existence of small fluctuations of signal  $\delta_{||}$  with mean characteristic times grouping around 2 h 40 min. The extrema of  $\delta_{||}$  occurred independently of the local time, and did not correlate with the start of observations (which lasted from 3 to 10 h continuously, depending on weather). This shows definitely that the effect is connected neither with periodic error in the drive of the coelostat nor with the possible heating of optics and misalignment between the main and the guiding system. Moreover, at the beginning of the work we made records of the signal  $\delta_{||}$  in two lines, the solar line ( $\lambda 5,123.7 \text{ \AA}$ ) and the telluric line ( $\lambda 5,901.5 \text{ \AA}$ ), simultaneously using both channels of the magnetograph to check if the effect was real or instrumental. One of these records, presented in Fig. 1, shows clearly that fluctuations arose from the Sun itself. We afterwards used only the solar line  $\lambda 5,123.7 \text{ \AA}$ .

To find the approximate periods of the fluctuation, we overlapped all fluctuations for the first nine days in August 1974 on the same graph to get the best fit (coincidence of maxima and minima) between them (see Fig. 2). This shows an almost sinusoidal wave of period  $\sim 2 \text{ h } 40 \pm 5 \text{ min}$ . We then applied superposed epoch analysis, and folded all data from

Fig. 1 Measurements of Doppler shift  $\Delta\lambda_v$  made on August 4, 1974, simultaneously on the solar line ( $\lambda = 5123.7$  Å, top) and telluric line ( $\lambda = 5901.5$  Å, bottom). The horizontal axis represents the local time.

August–September, with this approximate period 2 h 30 min–2 h 50 min (with the steps of 0.5 and 1 min) looking for the wave with minimum  $\sigma^2$  deviations. The best fit was for 2 h 40  $\pm$  0.5 min (Fig. 3). The mean amplitude of radial velocity  $v_{||}$  is  $\approx \pm 2$  m s $^{-1}$  so that the amplitude of pulsations is  $\approx 10$  km.

The observations made in October 1974 and March 1975 also showed the same periodicity occurred almost in phase with the data from August–September 1974 (stability over  $\sim 1,900$  periods). Therefore the period can be determined in fact with much higher accuracy than quoted above ( $\pm 0.5$  min).

### Interpretation

It is tempting to speculate about the results obtained. The systematic appearance of stationary periodic fluctuations in radial velocities of large (comparable with the radius of the disk) portions of the solar surface points definitely to pulsations of the Sun as a whole, and not to the rather stochastic processes of the ascent and descent of gigantic supergranules. The period 2 h 40 min is too long to be ascribed to the envelope of the Sun (the region where gravity acceleration  $g \approx$  constant), where the period would be no longer than 40–60 min. It also

cannot be ascribed to a set of standing oscillations on the solar surface<sup>4</sup>, because the effect does not depend on the phase of solar rotation. It cannot be a travelling wave around the Sun because the velocity of such a wave would be too high,  $\approx 140$  km s $^{-1}$ .

The simplest interpretation is that we observed purely radial pulsations. The most striking fact is that the observed period 2 h 40 min is almost precisely the same as that following from the simple formula of Ritter for radial pulsations  $\sigma^2 = (3\gamma - 4)g/R_\odot$  giving  $P = 2\pi/\sigma = 2$  h 47 min for  $\gamma = 5/3$ , almost the value if the Sun were to be an homogeneous sphere. (It should also be noted here that for more inhomogeneous models, for example when  $\rho \sim r^{-2}$  or on Roche's model, we would get much shorter periods.) The question can be considered more accurately using the results of Chandrasekhar and Lebowitz<sup>5</sup>, or those of Cox *et al.*<sup>6</sup> for the oscillations of polytropic gaseous spheres. It is easy to find from these results the dependence of  $\sigma^2/4\pi G\rho_m\lambda$  on the increase in density  $\lambda = \rho_c/\rho_m$  towards the centre of the Sun, which shows that periods decrease with increase of  $\lambda$  and of polytropic index  $n$  (as well as with  $3\gamma - 4$ ) for all different modes of oscillations (pulsational, transverse

Fig. 2 The best fit for the fluctuations from visual inspection of the records obtained during first 9 d of observations. Each point is the 5-min integrated signal of radial velocity (top). Averaging this gives the sine-like curve shown below.

shear, and toroidal, modes). For all these, the periods seem to be too short to be compatible with observations unless the polytropic index is not higher than  $n \approx 0.5$ . If, for a moment, we assume such a value of  $n$ , it would lead us to  $\lambda \approx 1.5$ ,  $\rho_c \approx 2$  and  $T_c \approx 6.5 \times 10^6$  K, and, at the mean molecular weight  $\mu = 0.6$  ( $X = 0.73$ ,  $Y = 0.26$ ,  $Z = 0.014$ )<sup>7</sup>, we would get such a low rate of energy generation  $\varepsilon$  from proton-proton reactions (see Reeves<sup>8</sup>, formula (3.6)) that the luminosity

$$L = \int_0^{R_\odot} \varepsilon(p, p) 4\pi r^2 \rho dr$$

would be  $\approx 2.5 \times 10^{29}$  erg s<sup>-1</sup>,  $\sim 10^4$  times smaller than the observed value.

### Possible explanation

We have investigated two possible solutions to this dilemma. The first alternative is that nuclear, and, in particular, (p,p) reactions are not responsible for energy generation in the Sun. Such a conclusion, although rather extravagant, is quite consistent with the observed absence of appreciable neutrino flux from the Sun<sup>9</sup>, and with the observed abundance of Li and Be in the solar atmosphere. The second alternative pointed out to us by D. Gough, (personal communication) is to adopt the current model of solar structure with (p,p) reactions and assume that we really observe not pure radial pulsations but some gravity  $g$  mode of quadrupole oscillation. (The possibility of deformations of the type was also pointed out to us by Schatzman at our preliminary report on this work at the colloquium at Meudon observatory, May 21, 1975.)  $g$  modes ( $l = 2$ ) can yield long period oscillations<sup>10</sup>, and according to Gough's calculations (private communication) the period of the  $g_{11}$  mode is in perfect agreement with our observed period 2 h 40 min. It seems strange, however, that this high harmonic is dominant.

We should keep in mind that our present method does not allow us to distinguish pure radial pulsations from quadrupole oscillations. Neither does it allow us to observe dipole ( $l = 1$ ) oscillations at all. Our observations do, however, give some hint of small amplitude oscillations of a shorter period overlapped on the main 2 h 40 min oscillation. Spectral analysis of corresponding data will be given elsewhere.

We are inclined to believe that the problem arising here is much the same as in the case of Cepheids discussed long ago

Fig. 3 Result of the superposed epoch analysis with 2 h 40 min period. Error bars represent r.m.s. deviations of individual measurements for each 10-min block of the data.

by Eddington<sup>11</sup> and Rosseland<sup>12</sup>, where the best agreement with observations can be reached for almost homogeneous spheres at  $\gamma = 5/3$ . We agree with Rosseland's conclusion that 'a thorough discussion of the problem on a new basis seems to be called for.'

We thank Dr D. Gough for helpful discussion of the paper before publication.

*Note added in proof:* Preliminary results of observations for 16 d in 1975 show the same periodicity in the mean magnetic field of the Sun, with an amplitude of 0.01 gauss.

*Theoretical periods of normal modes of vibration of the Sun are compared with the observed periods of oscillation of the solar surface. It is inferred from the comparison that it may soon be possible to use solar oscillations to measure aspects of the internal structure of the Sun.*

THE observational data that have been available for comparison with theoretical solar models are insufficient to enable stellar astrophysicists to ascertain the internal structure of the Sun. These data are just gross properties, such as the age, mass, radius, photon luminosity and neutrino luminosity, together

with details of the optical spectrum which are relevant only to the solar atmosphere. But recently there have been accurate measurements made of the frequencies of what are presumably normal modes of vibration of the Sun<sup>1-3</sup>. These dynamical data provide us with a new kind of information with which to probe the solar interior, and might lead to quite sensitive measures of certain aspects of the Sun's structure.

### Models of the Sun

Let us consider first how standard solar models are constructed. They are spherically symmetrical, and in hydrostatic and thermal balance. The assumption that the rotation rate in the

interior is comparable with that observed at the surface is usually made, which leads to negligible centrifugal forces and implies that spherical symmetry is a good approximation. This is consistent with the observed near circular shape of the solar image. It also leads to very low estimates of rotationally induced circulation currents. Thus, since solar models have convectively stable cores after the first few hundred Myr of their evolution on the main sequence, the products of thermonuclear reactions after that time are assumed not to have been transported away from the place where they were produced.

Models of stars of solar mass constructed from these assumptions predict a relationship between the photon luminosity  $L$  and time. This can easily be made consistent with the present solar luminosity  $L_{\odot}$  by adjusting the initial composition within the quite broad limits set by observation. Indeed, for any plausible initial abundance  $Z$  of heavy elements (usually assumed uniform) an initial hydrogen abundance  $X$  can always be found that reproduces  $L_{\odot}$ . The solar radius is not predicted because our ability to model the convection zone in the outer part of the star is inadequate. Instead convection theories are calibrated by adjusting solar models to have the correct radius at the appropriate age.

Thus, before the results of the attempt by Davis and his collaborators<sup>4,5</sup> to detect solar neutrinos were available, there was at least a single infinity of acceptable solar models, with varying  $Z$ , from which to choose. One of the roles of Davis' experiment was to help make the choice. It was not anticipated that the measured upper bound to the neutrino luminosity  $L_{\nu}$  would be a factor of  $\sim 10$  lower than the lowest theoretical predictions. Subsequently, models with low values of  $L_{\nu}$  were constructed<sup>6-13</sup>, though they did not satisfy all of the assumptions mentioned above. No doubt many more will emerge in the future. Some can be eliminated on theoretical grounds, such as those with hydrogen shells<sup>12</sup> or cores<sup>13</sup> which are Rayleigh-Taylor unstable, but the rest must be tested against new observations.

## Solar oscillations

An hypothesis that has received much attention in recent years is that the Sun has a rapidly rotating core. This has been pursued partly to produce models with low  $L_{\nu}$ , but principally to attempt to refute general relativity<sup>14</sup>. Careful observations of the oblateness of the quiet Sun by Hill and Stebbins<sup>15</sup> now makes the hypothesis unlikely. But these and other similar observations<sup>1,16</sup> have revealed that the apparent diameter of the solar image is oscillating, with a discrete spectrum of periods  $\lesssim 1$ h, and in the range of the low order  $p$  modes (acoustic modes). Severny, Kotov and Tsap<sup>2</sup> (in this issue of *Nature*) report observations of the difference between line of sight velocities at the poles and disk centre. This too is oscillatory, with a dominant period of 2 h 40 min, and is probably associated with a  $g$  mode (gravity wave). A spectrum of oscillations in a mean line-of-sight velocity has also been obtained recently by Brookes, Isaak and van der Raay<sup>3</sup> (also in this issue of *Nature*), who compared solar absorption lines with corresponding lines produced in the laboratory. The largest period observed is  $2.65 \pm 0.04$  h, in agreement with Severny *et al.* Fossat and Ricort<sup>36</sup> have recently reported large scale oscillations with a period of about 10 min.

Oscillations of the solar atmosphere have been observed before: the five-minute oscillations have been studied for more than a decade<sup>17</sup>, but these are probably a superposition of only those normal modes that have significant amplitudes in the extreme outer layers of the Sun (ref. 18, and H. Ando and Y. Osaki, unpublished), and so provide no direct information about the interior. Some 'long period oscillations' with periods of 40-50 min have also been detected<sup>19-22</sup>, but their periods were not accurately determined.

All the oscillations observed have too low an amplitude to influence the structure of the solar interior significantly, but their presence provides a new rich class of diagnostic data with which to compare the properties of theoretical models.

## Oscillations and solar structure

To what extent can the structure of the Sun be inferred from these comparisons? As a first step towards answering this question we have computed the low frequency ends of three spectra of  $p$  modes and the high frequency end of one spectrum of  $g$  modes. The  $p$  modes chosen have  $l = 0, 2$  and 4 and the  $g$  modes have  $l = 2$ , because these are the modes most likely to have been detected with the present techniques. The basic solar model was computed in the standard way with the program described by Eggleton<sup>23</sup>. With  $Z = 0.02$  and  $X = 0.735$  at zero age, and a mixing length of 1.10 pressure scale heights in Böhm-Vitense's<sup>24</sup> formulation of the mixing length theory, the model evolved to the present luminosity and radius in  $4.7 \times 10^9$  yr. The linearised oscillations were computed in adiabatic approximation in the manner described in ref. 25; non-adiabatic processes have a negligible influence on the frequencies of those modes with few nodes in the radial direction. The results are presented in Table 1, together with the frequencies of the peaks in the spectra reported by Hill, Stebbins and Brown<sup>16</sup>. To gain some idea of the sensitivity of the computed frequencies to variations in the basic solar model, the calculation was repeated with a heavy element abundance  $Z = 0.04$ . This required choosing  $X = 0.68$  at zero age and a mixing length of 1.325 pressure scale heights. The frequencies of a few of the modes are presented in Table 1 in parentheses. The frequencies in square brackets were obtained by changing the distribution of mesh points, and so indicate a lower bound to truncation errors.

Several features of Table 1 are noteworthy. First, it is clear that all but perhaps the lowest of the observed frequencies are approximately reproduced by the theory. This is evidence that the oscillations are not spurious and that most of them are indeed  $p$  modes. Not all the modes computed have been detected, however, though there is some evidence from the observed power spectrum displayed by Hill, Stebbins and Brown<sup>16</sup> for the existence of modes not listed in Table 1. For example, the  $p_4$  ( $l = 0$ ) and  $p_3$  ( $l = 2$ ) modes have frequencies near 0.63 mHz which is the position of a prominent shoulder in the power spectrum. Second, the frequencies of the radial ( $l = 0$ ) modes and the quadrupole ( $l = 2$ ) modes are very similar. Third, the effect on the  $p$  mode frequencies of changing  $Z$  is no greater than the observational uncertainties and the truncation errors in the calculations. The influence of composition changes on the  $g$  mode frequencies is somewhat greater, presumably because  $g$  modes are more concentrated towards the centre of the Sun, where the structure is more sensitive to the opacity. Indeed there is no  $g$  mode with  $l = 2$  (and none with  $l = 4$ ) with a period within the quoted errors of the observed period of 2 h  $40 \pm 1$  min when  $Z = 0.02$ , but there is when  $Z = 0.04$ . This cannot be considered as evidence for the higher  $Z$ , however, partly because the calculations are not sufficiently reliable, and partly because the identification of the mode may be incorrect: the oscillation may be a  $g_{10}$  ( $l = 2$ ) mode with  $Z \lesssim 0.02$ . (It is also evident that a very drastic change in the solar model would be necessary to enable the 2 h 40 min oscillation to be interpreted as the fundamental radial mode, as Severny *et al.*<sup>2</sup> and Brookes *et al.*<sup>3</sup> suggest. Indeed it is unlikely that any such model can be found that can generate the observed photon luminosity by thermonuclear reactions.)

## Future work

Although we are not yet in a position to draw definitive conclusions concerning the internal structure of the Sun from these observations, the results of this investigation do suggest that useful diagnostics from frequencies of oscillation will be available in the near future. To achieve this, greater accuracy must be attained from both the observations and the theory. Theorists have usually not considered it worthwhile to take the trouble to achieve high accuracy in the numerical integrations of the equations of stellar evolution, partly because our knowledge of opacities and nuclear reaction rates is uncertain and because

Table 1 Periods of solar oscillations (min)

1973	1975	$l = 0$		$l = 2$		$l = 4$		$l = 2$	
		Mode	Period	Mode	Period	Mode	Period	Mode	Period
52	47.9	$p_1$	62.7 (63.9)	$f$	46.0	$f$	39.6	$g_1$	55.1
		$p_2$	43.8	$p_1$	42.2 (42.3)			$g_2$	61.5
33	30.3	$p_3$	32.6 (31.8)	$p_2$	34.3	$p_1$	38.0	$g_3$	70.9
		$p_4$	26.0	$p_3$	26.7	$p_2$	29.3	$g_4$	81.8
23.8	21.0	$p_5$	21.0 [21.5]	$p_4$	21.5	$p_3$	23.4	$g_5$	93.0
		$p_6$	18.2	$p_5$	17.9	$p_4$	19.5	$g_6$	105
16.7	17.1	$p_7$	15.8 [15.4]	$p_6$	16.0	$p_5$	16.8	$g_7$	117
		$p_8$	14.0	$p_7$	14.1	$p_6$	14.6	$g_8$	130
13.3	11.8	$p_9$	12.5	$p_8$	12.6	$p_7$	13.0	$g_9$	142
		$p_{10}$	11.3	$p_9$	11.4	$p_8$	11.7	$g_{10}$	154 (147)
10.4	10.5	$p_{11}$	10.4	$p_{10}$	10.4			$g_{11}$	167 (159)
		$p_{12}$	9.55					$g_{12}$	180 (171)
9.2	8.8	$p_{13}$	8.84 [9.12]						
		$p_{14}$	8.52						
7.6	7.9	$p_{15}$	7.99						
		$p_{16}$	7.53						
7.0	7.2	$p_{17}$	7.12						
		$p_{18}$	6.75						
		$p_{19}$	6.41						
		$p_{20}$	6.10						

The periods headed 1973 and 1975 are from the observations reported by Hill, Stebbins and Brown<sup>16</sup>, and are accurate to  $\sim 5\%$ . Those periods not reported in the publication were kindly supplied by Professor Hill. Periods in the other columns were obtained theoretically using a solar model with  $Z = 0.02$ , except those in parentheses which are periods of oscillation of a model with  $Z = 0.04$ . The periods in square brackets were obtained by repeating the computation with  $Z = 0.02$  using a different distribution of mesh points. The classification of the modes, radial and non-radial, is according to the scheme proposed by Scuflaire<sup>34</sup> and Osaki<sup>35</sup>.

we cannot model thermal convection and other macroscopic motions reliably, and partly because there have been no observations that would distinguish between subtle differences in the models. But now the time has come to be a little more careful. Potential second-order accuracy difference schemes in some evolution programmes are spoiled, for example, by linearly interpolating opacity tables; this can quite easily be avoided. Accurate frequencies can be achieved by using variational principles on computed eigenfunctions. Also, more accurate observations are imminent. We do not know for how long a particular normal mode maintains an observable amplitude, but if it is many years, frequent observations over a long interval of time will yield very accurate periods. The observations by Severny *et al.*<sup>2</sup> and Brookes *et al.*<sup>3</sup> are a first step in this direction. Longer observing programmes are planned by Brown, Hill and Stebbins (personal communication) which may fix the  $p$  mode frequencies to within  $\frac{1}{4}\%$ , and make  $g$  mode periods measurable by their technique.

## Prospects

The prospect of such information is exciting, for it opens the possibility of a limited inverse problem of much the same kind as geophysicists pose to probe the internal structure of the Earth with seismic waves<sup>26,27</sup>. Because a spectrum contains so much information one can attempt to measure functions of radius  $r$  rather than just integral quantities such as luminosity. For example, given a certain set of assumptions such as hydrostatic support, thermal balance, an equation of state, opacities and nuclear reaction rates, one can seek that  $Z$  and that function  $X(r)$  that reproduces the observed spectra. If they do not

exist the assumptions must then be questioned: the answers may give a clue as to why standard solar models have been unable to yield neutrino fluxes consistent with Davis' observations.

To perform such an inversion, the modes exhibiting the observed frequencies must be correctly identified. It is apparent from Table 1 that it would be extremely difficult, if not impossible, to distinguish between  $p$  modes with  $l = 0$  and  $l = 2$  by frequency measurements alone, because the differences between their frequencies are less than variations that are produced by plausible changes in the composition of solar models. Instead,  $l$  must be measured directly, by observing the dependence of the amplitude and phase of the oscillations with position on the solar image. Hill and his collaborators plan to measure latitude dependence in the near future. This will yield several spectra, which in principle could be used to estimate simultaneously several functions such as  $X(r)$ . With enough spectra, a detailed model of the present Sun might be constructed without recourse to assumptions about the solar history. Of course since only finite portions of the infinite spectra can be measured, only limited resolution can be achieved, but with reasonable assumptions about smoothness one might hope to achieve considerably more reliable models than we have at present.

It is necessary to ask how many different oscillation spectra will be required to achieve this. The answer is not yet known, though Backus and Gilbert's<sup>27</sup> speculations on the geophysical inverse problem suggest that the number is somewhat greater (perhaps by almost a factor 2) than the number of functions to be measured. In any case, the reliability of the inferences increases with the number of spectra available.

It would thus be useful to add to the spectra that are currently being measured, the modes with  $l = 1$ . These modes are antisymmetrical about the Equator (assuming the axis of the mode coincides with the axis of rotation). The line-of-sight velocity varies with latitude  $\lambda$  as  $\sin 2\lambda$  and so vanishes at pole and Equator, but the technique described by Severny *et al.*<sup>2</sup> could presumably be modified to compare velocities at 45°N and 45°S. For Hill *et al.* to observe such a mode it would be necessary to observe the absolute position of the limb with respect to the other stars. This is more difficult than their present experiment, but may be possible in a year or so.

The driving of the oscillations must also be studied, for this can provide further diagnostic information just as the quality factors of seismic oscillations yield information about the dissipative properties of the Earth. Several studies of the growth or decay of normal modes of oscillation of the Sun have been reported<sup>25, 28–30</sup>, but the results are inconclusive. It is likely that the convection zone in the outer envelope is the seat of the excitation, because that is where the amplitudes of the oscillations are greatest. Spiegel<sup>31</sup> pointed out that the driving of non-radial  $p$  modes may take place in superadiabatic regions: this seems to be quite effective in the thin superadiabatic layer near the top of the zone for modes with high  $l$ , though the  $\kappa$ -mechanism, which drives the pulsations of Cepheids and RR Lyrae stars, is more important (H. Ando, and Y. Osaki, unpublished). It is likely that there is a superadiabatic region of much larger extent near the bottom of the convection zone, as is exhibited by models with mixing lengths that never exceed the distance from the nearest boundary of the convection zone<sup>32</sup> and is suggested by modal calculations of convection zones in A stars (J. Toomre, J.-P. Zahn, J. Latour, and E. A. Spiegel, unpublished). This may contribute towards driving modes with lower  $l$ . The direct influence of the convection itself is also likely to be important<sup>33</sup>, both in the way it modulates the heat flux and by the direct action of the Reynolds stresses. This presents a severe theoretical difficulty, as does the treatment of the reflection and transmission characteristics of the base of the corona. Indeed, these oscillations may be the principal source of energy maintaining the corona. It is important to inquire whether the continual interplay of these processes maintain the oscillations at approximately constant amplitude and phase, or whether, as some observations suggest<sup>20, 22, 36</sup>, the oscillations are triggered by occasional violent events such as flares, and then decay. If the former is the case, nonlinear pro-

cesses will determine the amplitudes; if the latter, it might be possible to approximate the decay using linear theory. In either case resonant interactions between modes may be important, and may explain why a particular mode is picked out from the closely spaced  $g$  mode spectrum. But whatever is occurring, the observed amplitudes will provide additional information that sooner or later will lead us to a better understanding of the Sun.

We thank T. M. Brown, J. P. Cox, H. A. Hill, M. E. McIntyre, M. L. Smith and R. T. Stebbins for useful discussions, and J. Toomre for reading the original manuscript and suggesting how it could be improved. J.C.-D. is grateful to Statens Naturvidenskabelige Forskningsraad of Denmark for financial support. D.O.G. thanks Dr P. A. Gilman for the hospitality of the Advanced Study Program of the National Center for Atmospheric Research, which is sponsored by the NSF.

# Observation of free oscillations of the Sun

J. R. Brookes, G. R. Isaak & H. B. van der Raay

Department of Physics, University of Birmingham, UK

*The Fraunhofer absorption lines for potassium and sodium on the Sun are compared with the corresponding lines in the laboratory using a resonant optical scattering method. The observed shifts between the Sun and laboratory lines may be interpreted in terms of the gravitational redshift (GRS), motion of the laboratory relative to the Sun and oscillatory terms which may be related to oscillations of the Sun.*

IN 1961, one of us proposed a new method for solar observation<sup>1</sup>, which has since been applied successfully<sup>2–4</sup>. The method is best illustrated with reference to Fig. 1: A circularly polarised absorption line, represented by the solid upper curve *a*, is incident on a K or Na vapour placed in a longitudinal magnetic field of such a strength as to place the anomalous Zeeman components, curve *b*, near the steepest parts of the solar absorption line. The intensity of resonantly scattered

light of left-handed polarisation is given by  $N_L$  whereas that for right-handed polarisation is given by  $N_R$ . It is clear from the figure that when there is no relative displacement between the solar and laboratory lines,  $N_L$  equals  $N_R$ . If, however there is a relative shift between the two lines, as illustrated by the dotted upper curve *a'*, the two intensities are no longer equal. Since the narrow laboratory Zeeman components overlap the steepest parts of the broader solar line, this method is extremely sensitive to small shifts.

## Apparatus

The apparatus was developed in Birmingham during 1973, and taken to the observatory at the Pic-du-Midi in France during the autumn of 1974, where the present data were recorded. Unfortunately, of the 12 days on which observation was possible, only 2 yielded data of sufficient quality and duration to allow

**Fig. 1** Upper: Schematic view of apparatus (see text) Lower: Principle of apparatus showing solar absorption line *a* and the position of the normal Zeeman components *b*. The dotted curve *a'* is for a shifted line.

for analysis. A small equatorially mounted servo controlled heliostat (1) directs integral solar light, appropriately filtered by a thermostatically controlled interference filter, (2) through a polariser (3) and electro-optical light modulator (4) which produce the requisite left- or right-handed polarisation, by the application of the appropriate electric potential. The light thus enters a vapour cell (5) situated in the field of a permanent magnet; the resonantly scattered light is detected by a cooled photomultiplier (6), and the processed output pulses are recorded on digital magnetic tape for subsequent computer analysis.

Integral solar light was used to reduce random shifts from the motion of individual granules of the Sun, the five-minute oscillation, and differential shifts across the rotating solar disk. Displacements caused by imprecise guiding and atmospheric turbulence also become less serious.

## Results

The recorded data thus consist of numbers of counts  $N_L$  and  $N_R$ , taken at approximately 0.5-s intervals. The difference between these data points over their sum  $[(N_L - N_R)/(N_L + N_R)]$  then gives a measure of the line shift corrected for any intensity

**Fig. 2** Data obtained on September 27, 1974 using a K cell.

fluctuation. Each data point consisted of  $\sim 5 \times 10^5$  counts, and the mean of 20 such ratios were taken, rejecting any pair which showed a gross deviation from that mean. Thus data points were obtained at 20-s intervals with a statistical accuracy of  $\sim 2 \times 10^{-4}$  which corresponds to a shift of  $\sim 1 \text{ m s}^{-1}$ . Results obtained on September 27, 1974 are shown in Fig. 2.

## Analysis

The observed shift of the solar absorption line relative to the laboratory line may be expressed in terms of velocities as

$$V_{\text{obs}} = V_{\text{orbit}} + V_{\text{spin}} + V_{\text{GRS}} + V(t) \quad (1)$$

where

$$V_{\text{orbit}} = (V_{\odot} - V_E) \cdot \mathbf{r}$$

is the resolved component of the relative velocity of the Sun and Earth along the unit radius vector  $\mathbf{r}$  joining their centres, with due allowance for planetary and lunar perturbations<sup>6</sup>. The observer's velocity, at a time  $t$ , relative to the Earth's centre along  $\mathbf{r}$  is given by

$$V_{\text{spin}} = V_{\lambda} \cdot \mathbf{r} = \omega_E R_E(\lambda) \cos \lambda \cos \delta \sin \frac{\pi}{12} (t - t_0) \quad (2)$$

where  $\omega_E$  is the angular velocity of the Earth,  $R_E(\lambda)$  is the observer's distance from the centre of the Earth,  $\lambda$  the latitude,  $t_0$  is local noon and  $\delta$  is the declination of the Sun.

The gravitational redshift is

$$V_{\text{GRS}} = \frac{GM_{\odot}}{c} \left( \frac{1}{R_{\odot}} - \frac{1}{R_{\odot E}} \right) - \frac{GM_E}{cR_E}$$

+ (terms due to second-order Doppler shifts)

where  $M_{\odot}$ ,  $M_E$ ,  $R_{\odot}$  and  $R_E$  are the Sun and Earth masses and radii respectively, and  $R_{\odot E}$  is the distance from the Earth to the Sun. The gravitational constant is given by  $G$  and the velocity of light by  $c$ .

Finally,

$$V(t) = V_0 + V_1(t)$$

where  $V_0$  represents time-independent shifts due to, for instance, collision effects in the Sun, and  $V_1(t)$  contains time-dependent terms such as solar oscillations which form the basis for this report.

The terms  $V_{\text{orbit}}$  and  $V_{\text{GRS}}$  in equation (1) may be regarded as essentially constant during any one day, whereas the  $V_{\text{spin}}$  term varies sinusoidally as illustrated by equation (2). The amplitude of this term is  $\sim 340 \text{ m s}^{-1}$  during the autumn at Pic-du-Midi.

The data of Fig. 2 clearly indicate the sinusoidal variation and provide an accurate calibration of the apparatus in terms of known parameters. It is further clear that the data pass through zero, indicating that at this time the solar absorption line and the laboratory line have a zero relative shift. Thus

$$-V_{\text{GRS}} = V_{\text{orbit}} + V_{\text{spin}} + V(t)$$

If it is assumed that  $V_1(t)$  terms are small or may be averaged out, then the gravitational redshift may be determined directly from this 'null' experiment in terms of known parameters. Details of this measurement will be reported elsewhere.

To investigate the  $V_1(t)$  terms, a two-parameter fit of the form

$$a + b \sin \frac{\pi}{12} (t - t_0)$$

was made to the data. The residuals, representing the differences between this fitted curve and the actual data points, were then found and are shown in Fig. 3 for the data obtained on September 27 using a K vapour cell. These data clearly suggest an

Fig. 3 Plot of residuals showing fitted 2.65-h oscillation.

oscillatory form for  $V_1(t)$  with a period between 2 and 3 h. A least squares fit to these points yielded a sine wave of amplitude  $2.70 \pm 0.24 \text{ m s}^{-1}$  and a period of  $2.65 \pm 0.04 \text{ h}$ . Similar data, but of lower quality, obtained on November 2 using a Na vapour cell gave an amplitude of  $4.5 \pm 0.7 \text{ m s}^{-1}$  for an oscillation of period  $2.7 \pm 0.1 \text{ h}$ .

The data of September 27 were further subjected to an autocorrelation and power spectrum analysis using a Hamming window. The resultant power spectrum, see Fig. 4, demonstrates clearly the existence of the 2.65-h period and suggests the presence of two or three further peaks whose amplitudes and periods are given in Table 1.

### Interpretation

The observed oscillations could be due to oscillations of the Sun or may be attributed to other effects. These other effects include the terrestrial atmosphere, nonlinearities in the apparatus, poor servo guiding, local voltage fluctuations, temperature instabilities and several more detailed instrumental effects. These causes, however, have been rejected after careful consideration of the types and magnitudes of variation that they might produce.

It is thus suggested that the 2.65-h period be identified with the gravest radial mode of oscillation of the Sun, the 58-min period with the fundamental non-radial mode and the 40-min

period with the second harmonic of the radial mode. The remaining peak in the power spectrum at 29 min can be traced to instrumental effects associated with the heliostat drive.

Extrapolation of the period-density relation of various pulsating stars<sup>8</sup>, if taken as a rough guide, places the expected period ( $P_0$ ) for the Sun  $1 \text{ h} < P_0 < 4 \text{ h}$ . Theoretical models of pulsations<sup>7-9</sup> indicate a similar, but narrower, range for the gravest radial mode, with the fundamental period  $P_0$  decreasing from 2.78 h to  $< 1 \text{ h}$  as the central density of the Sun increases. Current solar models<sup>9</sup> predict a period of  $\sim 1 \text{ h}$  corresponding to a steep density increase in the solar interior, in marked contrast to the observed 2.65-h period, which is consistent with a nearly homogeneous model of the Sun.

Table 1 Power spectrum of observed observations

Period	Observed amplitude ( $\text{m s}^{-1}$ )	Period predicted by homogeneous model
2.65 h	2.7	2.78 h: radial, fundamental
58 min	0.8	59 min: non-radial, fundamental
40 min	0.7	47 min: radial, second harmonic or 42 min: non-radial, second harmonic (instrumental)
29 min	0.5	

Fig. 4 Logarithmic power spectrum showing the four peaks above the  $3\sigma$  confidence level.

The value of  $P_0$  depends on the local velocity of sound,  $(\gamma kT/m)^{1/2}$ , integrated over the Sun, and if  $\gamma$  and  $m$  are presumed to be known,  $P_0$  becomes a measure of  $T$ , the mean temperature. The present value of  $P_0$ , assuming  $\gamma = 5/3$  and the usual composition for the Sun, yields a lower value for  $T$ , which in turn would produce a lower neutrino flux<sup>10,11</sup>.

If indeed the 58-min line is the fundamental of a non-radial mode of oscillation, then this line should be split by the rotation of the Sun<sup>12</sup>. Since the degree of splitting increases with the speed of rotation of the interior and since there is no evident splitting of the observed 58-min line, it may be concluded that the interior of the Sun rotates more slowly than once every 12 h.

The peak in the power spectrum corresponding to a 40-min period, is identified with the second harmonic of the radial mode. Oscillations of this period have been previously detected<sup>13</sup> and were also found with our apparatus during short bursts of good visibility at Birmingham during the spring of 1974.

The somewhat higher amplitude of the oscillations of November 2 for Na atoms, compared with that for K atoms on

September 27, is semi-quantitatively in agreement with expectations for a steady oscillation over this time interval. Sodium atoms in their ground state, being more abundant than potassium atoms, provide unit optical depth at a lower density in the solar photosphere, at which an unattenuated sound wave would have a higher velocity amplitude.

Each observation, taken separately, suggests that the damping is small ( $Q > 10$ ). If it is assumed that the oscillation observed on November 2 is a continuation of that first seen on September 27, and that no substantial excitation occurred during the intervening time, then  $Q$  becomes  $> 300$ , consistent with theoretical expectations<sup>14</sup>. The total energy content for the fundamental mode of oscillation integrated over the entire Sun is  $\sim 10^{31}$  erg, comparable with the energy of a major solar flare. In view, of the large  $Q$  for this mode of oscillation, however, the actual energy dissipated is negligible by solar standards.

The data could also be explained in terms of the high order  $g$  modes of non-radial oscillation<sup>15</sup>. These are predominantly horizontal and can have very long periods. It is difficult, however, to understand why other high order modes have not been detected unless some preferential excitation mechanism exists.

Hill<sup>16</sup> has reported the detection of solar oscillations during his measurements on solar oblateness. The periods reported are all  $< 1$  h and the amplitudes at least an order of magnitude greater than those reported here. It seems difficult to reconcile these data with our work, unless the oscillations are of high

order, so that averaging over the whole solar disk reduces their velocity amplitude substantially.

Improvements in the measurements may help to cast some light on the internal rotation of the Sun and thereby on the Einstein and Dicke theories of gravitation<sup>17</sup>. An extension of the work using a two-dimensional spectrometer capable of measuring wavelength shifts across the solar disk may well inaugurate a new field—the probing of the Sun's interior with seismic waves, analogous to its terrestrial counterpart<sup>18</sup>.

We thank C. Djokic, C. P. McLeod for assistance and Professor J. Rösch for hospitality and interest. We thank the SRC for financial support and a research associateship to J.R.B.

*In one southern Italian and one Pakistani patient with homozygous  $\beta_0$  thalassaemia in which no detectable  $\beta$ -globin synthesis occurs and no  $\beta$ -globin messenger RNA is found, the gene for  $\beta$  globin has been shown to be present using complementary DNA. This demonstrates that for these patients the imbalance in chain synthesis is not attributable to a gene deletion.*

THALASSAEMIA is a common hereditary anaemia which is caused by imbalanced synthesis of  $\alpha$ - and  $\beta$ -globin chains<sup>1</sup>. In  $\alpha$  thalassaemia there is reduced synthesis of  $\alpha$ -globin, which in at least some cases results from a partial or complete deletion of the  $\alpha$ -globin genes<sup>2–4</sup>. Other cases of  $\alpha$  thalassaemia are caused by chain termination mutants for which the globin chain is synthesised in very small amounts<sup>5</sup>.

$\beta$ -Thalassaemia is a more complex hereditary condition, since the decrease in  $\beta$ -globin synthesis can be compensated by increased synthesis of  $\delta$  and  $\gamma$ -globin chains (as in  $\beta_0$  thalassaemia) or  $\gamma$ -globin chains only (as in  $\delta\beta_0$  thalassaemia). In cases

of  $\beta^+$  thalassaemia low levels of  $\beta$ -globin synthesis are observed, whereas in  $\beta_0$  thalassaemia no  $\beta$ -chain synthesis occurs and only haemoglobins  $A_2$  (HbA<sub>2</sub>) and F (HbF) are found in the peripheral blood. In some cases of  $\beta_0$  thalassaemia, messenger RNA (mRNA) for  $\beta$  globin is absent as judged by hybridisation to complementary DNA (cDNA) prepared using viral reverse transcriptase<sup>6</sup> and also by translation in cell-free protein synthesis systems<sup>7</sup>. In one form of  $\beta_0$  thalassaemia, from the Ferrara region of Italy,  $\beta$ -globin mRNA (mRNA <sub>$\beta$</sub> ) is present in erythroid cell cytoplasm but is not translated<sup>8</sup>.

We have isolated DNA from spleens of two patients with homozygous  $\beta_0$  thalassaemia. In neither case was there any demonstrable synthesis of  $\beta$  globin in the peripheral blood, nor could mRNA <sub>$\beta$</sub>  be detected in the cytoplasmic RNA of spleens or peripheral blood cells. In both cases, however, the hybridisation of cellular DNA to a DNA enriched in sequences specific for  $\beta$ -globin genes (cDNA <sub>$\beta$</sub> ) was identical to that of normal DNA, demonstrating the presence of substantially intact genes for  $\beta$  globin in homozygous  $\beta_0$ -thalassaemic patients.

This confirms our previous report of the presence of  $\beta$ -globin genes in the genetically more complex double heterozygote for

**Fig. 1** Globin synthesis in homozygous  $\beta_0$  thalassaemia. Washed red blood cells from the Pakistani patient with homozygous  $\beta_0$  thalassaemia were incubated in the presence of  $^3\text{H}$ -leucine (specific activity 40–60 Ci mmol $^{-1}$ , Radiochemical Centre) as described previously<sup>15</sup>. Extracted whole-cell globin was chromatographed on carboxymethylcellulose<sup>10</sup>. Aliquots of the column fractions were monitored for absorption at 280 nm and for radioactivity. Essentially no radioactivity (-----) associated with absorbance (—) was seen in the  $\beta$ -globin region (arrow:  $\beta$ -globin peak fraction from parallel marker run). Identical results were obtained with red blood cells from the Italian patient.

$\beta_0/\delta\beta_0$  thalassaemia, for which at least one of the haploid genomes was shown to contain a largely intact  $\beta$ -globin gene<sup>9</sup>. It remains to be determined whether the small deficit in  $\beta$ -gene hybridisation shown for that genome is due to a partial deletion in the haploid  $\delta\beta_0$ -globin gene region.

Spleens were removed for therapeutic reasons from two patients with  $\beta_0$  thalassaemia, for both of whom genetic data confirmed the haematological diagnosis. One patient was of southern Italian origin and the other from Lalipur, Pakistan. In both cases incubation of peripheral blood with  $^3\text{H}$ -leucine followed by globincha in separation on carboxymethylcellulose columns in 8 M urea-mercaptoethanol-phosphate buffer systems, pH 6.7 (ref. 10) showed  $\alpha$ - and  $\gamma$ -globin chain synthesis only. No  $\beta$ -globin synthesis was observed (Fig. 1, Pakistani patient; identical data were obtained from the Italian patient). In both cases, both parents showed elevated levels of HbA<sub>2</sub>.

Nuclear DNA was prepared from spleen using hydroxylapatite-urea as described previously<sup>2,11</sup>. Normal DNA was prepared either from non-thalassaemic spleen or from normal placenta. The DNA was fragmented to approximately 200–300 nucleotides in length either by sonication as described previously<sup>11</sup> or by boiling for 20 min in 0.3 N NaOH<sup>12</sup>.

Normal adult human globin mRNA (mRNA $^{\alpha,\beta}$ ) was prepared from reticulocyte-rich blood from a patient with a non-thalassaemic haemolytic anaemia. Cord exchange transfusion blood was obtained from newborn infants with Rhesus incompatibility, and used to prepare mRNA $^{\alpha,\gamma,\beta}$ .  $\alpha$ -Thalassaemia globin mRNA (mRNA $_{\text{HbH}}$ ) was obtained from blood from a patient with haemoglobin H disease<sup>2,9,13</sup>. Total  $\beta_0$ -thalassaemia cytoplasmic RNA (RNA $_{\beta_0\text{thal}}$ ) was prepared by phenol-chloroform extraction from  $\beta_0$ -thalassaemic spleen postnuclear supernatant<sup>9</sup>.

cDNA was prepared from the various mRNAs as template, using oligo(T) as primer with avian myeloblastosis virus reverse transcriptase as described previously<sup>14</sup>. The labelled nucleoside triphosphate used was  $^3\text{H}$ -dCTP (specific activity 25–27 Ci mmol $^{-1}$ ; Radiochemical Centre).

All cDNAs prepared from mRNAs hybridised back to their respective templates showing approximately 5–10% apparent double-stranded material in the absence of RNA and 10–15% material which did not hybridise even in great mRNA excess.

Complementary DNA enriched in sequences complementary to mRNA $_{\beta}$  was prepared by annealing cDNA $_{\text{HbH}}$ , which is already rich in cDNA $_{\beta}$ , to the cytoplasmic mRNA from the

previously described case of  $\delta\beta_0/\beta_0$  thalassaemia, which contains no detectable mRNA $_{\beta}$  sequences. The non-hybridising sequences (cDNA $_{\beta}$ ) do not bind to hydroxylapatite in 0.12 M sodium phosphate buffer, and were collected, concentrated and characterised as described previously<sup>9</sup>.

Three cDNA $_{\beta}$  probes were used in the experiments described below. cDNA $_{\text{HbH}}$  was approximately 80% cDNA $_{\beta}$  sequences. cDNA $_{\beta}$  cycled through hydroxylapatite as described above was >80% pure in one case and >90% in the other, as judged by hybridisation to  $\delta\beta_0/\beta_0$ -thalassaemic total cytoplasmic RNA<sup>9</sup>. Both cDNA $_{\beta}$  preparations showed plateau levels of approximately 70% when hybridised to a large excess of mRNA which contained  $\beta$ -globin. This reduction in plateau level was due to enrichment of non-hybridising material during hydroxylapatite purification of these cDNA $_{\beta}$  (ref. 9).

No  $\beta$ -globin mRNA was detected in the spleen cytoplasmic RNA from each patient (Figs 2 and 3). At a  $1 \times 10^6$ -fold

**Fig. 2** Hybridisation of  $\beta_0$  spleen (Pakistani patient) total cytoplasmic RNA with cDNA $_{\alpha,\beta,\gamma}$  and cDNA $_{\beta}$ . Total cytoplasmic RNA from  $\beta_0$  spleen was prepared from the post-nuclear supernatant of spleen homogenate by phenol-chloroform extraction<sup>9</sup>. mRNA was prepared by affinity chromatography with oligo(dT)-cellulose (Collaborative Research) from total RNA prepared by phenol-chloroform extraction of foetal, and HbH disease, whole red blood cells. DNAs were prepared to these mRNA templates, using RNA-dependent DNA polymerase from avian myeloblastosis virus (AMV), as described previously<sup>9,14</sup>.  $^3\text{H}$ -dCTP (Radiochemical Centre) of specific activity 27 Ci mmol $^{-1}$  was the only labelled nucleotide present. Specific activity of the cDNAs was 16,100 c.p.m. ng $^{-1}$  at a counting efficiency of 38%. cDNA $_{\text{HbH}}$  was used to prepare cDNA $_{\beta}$ , by hybridisation to a 10,000-fold excess of  $\delta\beta_0/\beta_0$  total cytoplasmic RNA, followed by isolation of the unhybridised, single-stranded fraction by chromatography on hydroxylapatite<sup>9</sup>. Purity of cDNA $_{\beta}$  was estimated to be >80% (see text). A constant amount of 0.05 ng cDNA $_{\alpha,\beta,\gamma}$  or cDNA $_{\beta}$  was hybridised with increasing amounts of  $\beta_0$ -spleen cytoplasmic RNA, in a volume of 2  $\mu\text{l}$  50% formamide, 0.5 M NaCl, 25 mM HEPES buffer, pH 6.8, 1 mM EDTA, containing 2.5 mg ml $^{-1}$  *Escherichia coli* RNA. Samples were sealed in silicone-coated glass capillaries, and incubated at 43°C for 168 h. Percentage of cDNA which had hybridised was determined by assay with the single-stranded-specific nuclease, S1, followed by perchloric acid precipitation of hybridised material. Hybridisation of cDNA $_{\alpha,\beta,\gamma}$  (●) and cDNA $_{\beta}$  (▲) to increasing amounts of  $\beta_0$ -spleen cytoplasmic RNA is shown. Both cDNAs contain a double-stranded component of approximately 11%. Hybridisation of both cDNAs, in the same conditions, to a  $1 \times 10^6$ -fold excess of *E. coli* RNA, still gave values of 11% for the double-stranded component.

excess of  $\beta_0$ -cytoplasmic RNA, cDNA $_{\beta}$  and cDNA $_{\text{HbH}}$  hybridised to approximately 12% above background, indicating a virtual absence of  $\beta$ -globin sequences. The low level of hybridisation of the  $\beta$ -enriched cDNAs is attributable to contaminating  $\alpha$ - or  $\gamma$ -globin sequences in the cDNA hybridising to their complementary sequences in the  $\beta_0$ -cytoplasmic RNA.

In contrast,  $\alpha$ - and  $\gamma$ -globin sequences were readily detected by the cDNA $_{\alpha,\beta,\gamma}$  (Fig. 2) and cDNA $_{\alpha,\beta}$  (Fig. 3) in both preparations of spleen  $\beta_0$ -cytoplasmic RNA at RNA-cDNA ratios as low as  $1 \times 10^5$ . The fact that cDNA $_{\alpha,\beta}$  and cDNA $_{\alpha,\beta,\gamma}$

**Fig. 3** Hybridisation of  $\beta_0$ -thalassaemic spleen (Italian patient) total cytoplasmic RNA with  $cDNA_{HbH}$  and  $cDNA_{\alpha, \beta}$ .  $\beta_0$ -spleen cytoplasmic RNA,  $cDNA_{HbH}$  and  $cDNA_{\alpha, \beta}$  were prepared as described in Fig. 2.  $cDNA_{HbH}$  was estimated to contain 80%  $\beta$ -globin sequences<sup>9</sup>. A constant amount (20 pg) of  $cDNA_{HbH}$  ( $\blacktriangle$ ) or  $cDNA_{\alpha, \beta}$  ( $\bullet$ ) was hybridised with increasing amounts of  $\beta_0$ -spleen cytoplasmic RNA in 1  $\mu$ l hybridisation buffer at 43 °C for 10 d. Proportion of cDNA rendered resistant to S1 nuclease digestion was determined. Both  $cDNA_{HbH}$  and  $cDNA_{\alpha, \beta}$  hybridised to 80–85% to their respective templates.

do not hybridise to levels greater than 50–60%, however, is further evidence for the absence of  $\beta$ -globin sequences.

Hybridisation to total normal and  $\beta_0$ -thalassaemic DNA was carried out in  $cDNA_{\beta}$  excess. Figure 4 shows the rate of reannealing of the  $cDNA_{HbH}$  to the DNA from the Pakistani patient. The curves for normal and  $\beta_0$ -thalassaemic DNA are essentially identical.

To demonstrate with greater rigour the equivalence of the thalassaemic and normal DNAs, the extents of hybridisation were determined for, both cases at a number of different  $cDNA$ -DNA ratios. At low ratios of  $cDNA_{\beta}$ -total DNA, the effects of contaminating  $\alpha$ - and  $\gamma$ -globin  $cDNA$  sequences will be greatly reduced. At ratios varying from 6 pg  $cDNA_{\beta}$  to 100  $\mu$ g total DNA to 70 pg  $cDNA_{\beta}$  to 100  $\mu$ g total

**Fig. 4** Hybridisation of excess  $cDNA_{\beta}$  to normal and  $\beta_0$  DNA (Pakistani patient) DNA was prepared from normal and  $\beta_0$  spleen, and fragmented to a mean size of 200–300 nucleotides single-stranded length, by sonication, as described previously<sup>8,11</sup>. Samples of 2.16 mg normal, or  $\beta_0$  DNA, and 0.5 ng  $cDNA_{\beta}$  were lyophilised and dissolved in 0.12 M sodium phosphate buffer, pH 6.8, at a DNA concentration of 5 mg ml<sup>-1</sup>. Aliquots (43  $\mu$ l) (one-tenth total volume) were sealed in silicone-treated glass capillaries, boiled for 10 min, and incubated for various times at 60 °C. At selected times, contents of capillaries were expelled with 210  $\mu$ l S1 nuclease assay buffer and stored at -20 °C until assayed with S1 nuclease to determine the proportion of  $cDNA$  which had hybridised<sup>9</sup>. A background S1 resistance of approximately 2% has been subtracted, and percentage hybridisation has been calculated relative to the maximum amount of hybridisable  $cDNA_{\beta}$  (70%).  $\bullet$ ; Percentage  $cDNA_{\beta}$  hybridised to normal DNA;  $\blacktriangle$ , percentage  $cDNA_{\beta}$  hybridised to  $\beta_0$  DNA.

DNA the extent of hybridisation is the same for the normal and the two thalassaemic DNAs (Fig. 5).

Analyses of both thalassaemic DNAs with  $cDNA_{\alpha, \gamma, \delta}$  in excess demonstrated a complexity of the total globin genes identical to that of normal DNA<sup>9</sup>.

We have previously demonstrated cross hybridisation between  $\beta$ -globin and  $\delta$ -globin gene sequences<sup>9</sup>. It is known from genetic<sup>1</sup> and molecular<sup>9</sup> analyses that there are single copies of each of these genes, and a deletion of the  $\beta$ -globin gene would be apparent as a 50% reduction in extent of hybridisation and greater than 50% reduction (because of mismatching) in rate of hybridisation. The identity of the hybridisation for normal and thalassaemic DNAs demonstrates that no substantial deletion of the  $\beta$ -globin gene has occurred.

**Fig. 5** Hybridisation of  $cDNA_{\beta}$  to normal and  $\beta_0$  DNAs as a function of  $cDNA$ -DNA ratio. Normal or  $\beta_0$ -thalassaemic DNA was prepared from spleens as described in Fig. 3, except that fragmentation to 200–300 nucleotides was achieved by boiling in 0.3 N NaOH for 20 min.  $cDNA_{\beta}$  (>90% pure) was mixed at the indicated ratios with normal or thalassaemic DNA (50–250  $\mu$ g) in 0.12 M sodium phosphate buffer, pH 6.8, 1 mM EDTA, at a DNA concentration of 5 mg ml<sup>-1</sup>. Mixtures were sealed in capillaries, heated to 100 °C for 10 min, and incubated at 68 °C for 5,200 min. Samples were diluted with S1 nuclease assay buffer (500  $\mu$ l per 100  $\mu$ g DNA) and assayed with S1 nuclease to measure the proportion of  $cDNA$  hybridised<sup>9</sup>. A background S1 resistance of 2% has been subtracted, and the percentage of  $cDNA_{\beta}$  hybridised has been calculated relative to the maximum amount of hybridisable  $cDNA_{\beta}$  (70%). Results are shown as pg  $cDNA_{\beta}$  hybridised per 100  $\mu$ g DNA as a function of  $cDNA$ -DNA ratio.  $\bullet$ , Normal DNA;  $\circ$ ,  $\beta_0$ -thalassaemic DNA (Italian patient),  $\blacktriangle$ ,  $\beta_0$ -thalassaemic DNA (Pakistani patient).

Since the  $cDNA_{\beta}$  used in these experiments is not a complete copy of the mRNA <sub>$\beta$</sub> , a deletion near to the initiation region of transcription, to the 5' end of the mRNA, would be more difficult to detect. A deletion in a non-transcribed portion of the genome which might still be involved in the control of transcription could not be detected using these techniques.

$\beta_0$  thalassaemias from other areas (for example, Ferrara<sup>8</sup> and of Chinese origin<sup>10</sup>) contain globin mRNA sequences which are untranslated. This result for homozygous  $\beta_0$  thalassaemia from two separate geographical locations is in marked contrast to the previous demonstration that a gene deletion is the primary cause of south-east Asian homozygous  $\alpha_0$  thalassaemia. It is still not clear whether transcription of the  $\beta$ -globin RNA sequence is completely absent, either because of a mutation in the initiation region for transcription or a mutation of a necessary control element, or if transcription occurs but the mRNA <sub>$\beta$</sub>  sequences are either not processed from nucleus to cytoplasm or are broken down very rapidly without translation.

The Beatson Institute for Cancer Research is supported by the MRC and the Cancer Research Campaign. The Nuffield Department of Clinical Medicine thanks the MRC for support.

We thank Dr Beard (St Petersburg, Florida) for AMV, and Drs A. Neinhuis (NIH), C. S. Pitcher (Aylesbury, UK), G. Gazzola and M. Nowakova (Clinica Pediatrica, Milano) for clinical and pathological material.

## Transient X-ray source A1118—61

THE transient X-ray source Ariel 1118—61 was discovered late in 1974 (refs 1, 2). It has been suggested<sup>3</sup> that this source may be associated with the long period Mira-type variable RS Cen, which is located within the error box for the X-ray source. The proposed mechanism of X-ray generation was accretion on to a compact object in orbit around the variable star. The periodic variation in the radius of the star would lead to a variable accretion rate at the orbit of the compact object, and give rise to a variable X-ray flux. This suggestion has two important consequences. First, it raises the possibility that some, at least, of the apparently transient X-ray sources can be explained by similar phenomena. For instance, Barnden and Francey<sup>4</sup> and Shukla and Wilson<sup>5</sup> reported the presence of two presumably 'transient' X-ray sources in the constellation Cetus. The error box for each source (Cetus X-1 (ref. 4) and Cetus X-2 (ref. 5)) was large,  $\sim 10$ – $15^\circ$  diameter, but they did just overlap. Of significance here is the fact that the overlap area is centred on O Ceti (Mira), the type star of this class of variables. The two observations were at similar phases (0.12 and 0.22) of the variable, but separated in time by  $\sim 1$  cycle. The difference in phase of the Centaurus and Cetus transients is easily explained by differences in orbit size and expansion velocity.

The second consequence of Fabian *et al.*'s proposed identification is a clear, experimentally testable prediction, that the X-ray source should be observable at intervals of  $\sim 164.5$  d after the outburst observed by Ariel V.

We have used the collimated proportional counter on board Copernicus to test this prediction. The detector was pointed at A1118—61 on June 8, 1975 between 17 h 9 min and 22 h 15 min, a time corresponding to an eclipse of the nearby binary X-ray source Cen X-3. No signal was detected above background during the whole of the observing session. Our 90% confidence upper limit to the source strength in the energy band 2.5–7.5 keV is  $3 \times 10^{-11}$  erg cm<sup>-2</sup> s<sup>-1</sup>; this is 1.7% of the peak flux reported by Ariel V in the same energy band. Thus it is likely that the X-ray source A1118—61 is not connected with RS Cen, unless for some reason the X-ray generation was turned off during the time when Copernicus was observing the source.

Copernicus observed Cen X-3 on January 30, 1974 precisely 2 periods of RS Cen before the peak of the outburst reported by Ariel V. A1118—61 was well within the field of view of the detector, so we have been able to search for a signal from it during the binary down state of Cen X-3. Again, no signal was detected above an upper

limit of  $2 \times 10^{-10}$  erg cm<sup>-2</sup> s<sup>-1</sup> ( $\sim 10\%$  of peak Ariel V flux) in the energy band 2.5–7.5 keV. Thus there is no strong case for an association of A1118—61 with RS Cen, based on the mechanism suggested by Fabian *et al.*<sup>3</sup>

We have also searched for X rays from A1118—61, using Copernicus, at a time well removed from the hypothesised critical phase. The observations were made between April 1975 6 d 23 h 31 min and 7 d 3 h 33 min, again during a binary down state of Cen X-3. On this occasion, too, we were unable to detect the source. Our 90% confidence upper limit on this occasion of  $\sim 9 \times 10^{-11}$  erg cm<sup>-2</sup> s<sup>-1</sup> in the energy band 2.5–7.5 keV is again substantially below the peak Ariel V flux of  $1.8 \times 10^{-9}$  erg cm<sup>-2</sup> s<sup>-1</sup>.

Our upper limits should clearly be borne in mind in any attempts to explain this source. In particular, Pacini and Shapiro<sup>6</sup> have suggested that it is the motion of the compact object in an eccentric orbit which periodically brings the compact object close enough to the primary for accretion rates to become appreciable (this scheme has also been suggested by Clark *et al.*<sup>7</sup> and Davison and Tuohy<sup>8</sup> to explain the long term behaviour of Cir X-1). Our upper limits modify some of the constraint equations developed by Pacini and Shapiro for the parameters of the proposed binary system. The June 8 upper limit of 1.7% of the peak flux leads immediately to a lower limit of  $\sim 0.8$  for the orbital eccentricity, as compared with the value of 0.4 derived by Pacini and Shapiro. This higher value of eccentricity also does not seem to be excluded by the theory developed by Wheeler *et al.*<sup>9</sup>, though we note that practically any value for the final eccentricity may be predicted, given a suitable (and not impossible) choice of initial conditions

## New X-ray measurements of the Crab spectrum in the range 26 keV–1.2 MeV

THE Imperial College scintillation detector on Ariel V made measurements of the X-ray spectrum of the Crab Nebula in 1975 April and September. The detector consists of an  $8\text{ cm}^2 \times 4\text{ cm}$  CsI(Na) crystal actively collimated to  $8^\circ$  FWHM, and measures X rays in 15 logarithmically spaced energy channels in the range 26 keV–1.2 MeV. The detector axis is inclined  $3^\circ$  to the spacecraft spin axis, which in turn is normally offset by  $\sim 3^\circ$  from the source being viewed. Source counts are thus spin modulated, allowing the background to be subtracted. A residual modulation is further removed by changing the direction of the offset to the source and observing the resulting phase change in the modulation. This observational technique ensures all sources of background are eliminated, the modulation characteristics having been previously determined by laboratory calibration.

Counting rates were then deconvolved from the detector response by considering the effects due to window thickness, crystal dead layer and K shell X-ray escape, as well as the

various statistical processes that occur in the detection sequence from the incident photon to the phototube output.

The 1975 observations of the Crab Nebula were first analysed separately, but as no significant variation was observed they have been combined in Fig. 1. Error bars represent  $1\sigma$  counting statistics, which we believe dominate any other systematic errors. Also plotted on this figure are data below 20 keV obtained from a rocket flight by Toor and Seward<sup>1</sup> in 1970, and results above 1 MeV from balloon flights by Baker *et al.*<sup>2</sup> in 1972 and Schonfelder *et al.*<sup>3</sup> in 1974.

Though there have been many studies of the Crab Nebula by balloon and rocket experiments observing at  $< 100\text{ keV}$  (see ref. 2) and some limited observations above 1 MeV, there has previously been a noticeable lack of any accurate observations between these two ranges.

The dotted line shown in Fig. 1 is the best fit given by Toor and Seward to all available data and extrapolated from their limit of  $\sim 50\text{ keV}$  up to 10 MeV. As can be seen, the fit to the Ariel V results is excellent up to 500 keV and lies within one s.d. of the final point at 840 keV. Our results are thus consistent with a power law extrapolation to beyond 1 MeV, and hence with Schonfelder's upper limits. On the other hand, if Baker's results are correct, this would imply a rather abrupt hardening of the spectrum at about 800 keV, with a consequent softening above 10 MeV to bring the spectrum into agreement with spark chamber measurements by Kniffen *et al.*<sup>4</sup> at 50–100 MeV.

## Meteor radar rates and the solar cycle

A WORLDWIDE increase in meteor echo rates in 1963 was observed in New Zealand<sup>1</sup>, Canada and Sweden and has been widely discussed in the literature<sup>2–8</sup>. From radar observations in 1953–66 I reported<sup>9</sup> a long term variation in the echo count rate with a peak occurring in 1963 near the solar minimum. Those observations also showed that the height of first appearance of meteors from a given shower had remained nearly constant at  $\sim 110\text{ km}$ , whereas the average endpoint height had risen by  $\sim 11\text{ km}$  from 1956 to 1963. It was thus evident that the 1963 peak in the meteor echo count rate was of atmospheric origin. We report here further observations, and propose that the phenomenon can be explained by a solar controlled variation of the atmospheric density gradient at the meteor ablation level, probably caused by a variation in the solar X-ray flux.

My observations were made at the Onsala Space Observatory in the period 1953–72. Visual and radar recordings of meteors have been regularly made in August since 1953. A radar control run in September was operated intermittently from 1953 to 1959 and has been regularly performed since 1962. The radar equipment records echoes of duration  $\geq 0.02\text{ s}$  corresponding to meteors brighter than about fifth zenithal magnitude. The experimental technique has been described elsewhere<sup>5,10</sup>.

Figure 1a depicts the mean night-time hourly rate of meteor radar echoes of all durations, as observed from 1953 to 1972 (1954 is missing and 1971 not yet reduced). A long term variation in the August meteor rate curve is evident. The operational run in August includes the period of maximum activity of the Perseid meteor shower, but the length of the run is such that

the observed total echo rates may be considered a measure of sporadic meteor activity. It is also evident that total echo rates for the control period in September, when no prominent shower is active, exhibit similar temporal variations. It is therefore concluded that the observed time variation in meteor rates is representative of meteor rates in general. Figure 1 suggests a variation by a factor of  $\sim 2$  in the echo rate curve with peaks primarily confined to times near solar minimum, and further compares the total radar rate curve with the mean endpoint height and trail length of meteors of a given shower. These meteors represent a homogeneous sample with respect to velocity, angle of incidence and composition. It is evident that the meteor endpoint heights and meteor radar rates exhibit similar temporal variations. There is further an inverse relationship between radar rates and the mean trail length of meteors (Fig. 1c). We found that the echo amplitudes showed a temporal variation similar to that of the radar rates.

Fig. 1 Comparison between meteor echo rates, meteor endpoint heights and meteor trail lengths. *a*, Mean night-time hourly rate of meteor radar echoes of duration  $> 0.02$  s observed in August (●—●) and September (○) during the period 1953–72. Radar observations were made at a frequency of 33 MHz. *b*, Mean endpoint height of Perseid meteor trails determined from combined radar and visual observations. *c*, Mean trail length of Perseid meteors.

Figure 1 suggests a dependence of radar rates on position in the solar cycle. The phase of the solar cycle variation is analysed in the periodogram in Fig. 2. The zero epoch in the diagram is that of the sunspot maximum. It is evident that the highest radar rates are observed 4–6 yr after a solar maximum and the lowest, 1–2 yr before a solar maximum. This result is consistent with those of an analysis of visual meteor rates (1844–1933) published by Bumba<sup>11</sup>. The scale in Fig. 2 may be approximately referred to solar minimum by subtracting 6.5 yr. One may therefore conclude from Fig. 2 that the phase of the radar rate curve is such that peak meteor rates are observed 1–2 yr before a solar minimum.

Fig. 2 Variation of meteor radar rates with position in the solar cycle. Epochs of sunspot maxima are 1957.9 and 1968.9. All time differences in the diagram have been rounded off to an integer number of years.

A long term variation in radar rates, meteor trail length and radar echo strength may be qualitatively explained if it is assumed that the density gradient of the neutral atmosphere between 85 and 110 km varies periodically with position in the solar cycle. If the density gradient is increased near solar minimum, the meteor ablation process will occur over a shorter

Fig. 3 Mean night-time hourly rate of meteor radar echoes (upper diagram); mean monthly non-flare 2–12 Å solar X-ray flux after Wende (lower diagram).

length of trail and a larger electron line density will result from a particular meteoroid. This will increase the echo signal strength and thus allow smaller meteors to come within the detection threshold of the radar, thereby producing an increase in the total echo rates.

The observed temporal variation of meteor trail length provides information on the variation of the atmospheric density scale height. The length of a meteor trail may be written<sup>12</sup>

$$L = cH \sec z_R \quad (1)$$

where  $L$  and  $H$  are meteor trail length and atmospheric scale height, respectively;  $z_R$  is the zenith distance of the radiant and  $c$  is a numerical constant, which depends on mass, velocity and limiting visual magnitude. Insertion of  $H = 5.7$  km,  $L = 28.2$  km and  $\sec z_R = 1.40$  gives  $c = 3.53$ . Observed maximum and minimum values of trail length were 37.5 km for 1955 and 22.7 km for 1964. On the basis of the data it is tentatively suggested that the average density scale height at the meteor ablation level has varied from about 7.5 km in 1955 to 4.5 km in 1964.

The heating mechanism required to produce a solar cycle effect in the atmospheric density gradient at the meteor ablation level is not properly understood. A long term variation in the X-ray and particle flux emitted from the Sun seems to be the most probable cause. Kreplin<sup>13</sup> has summarised the available rocket and satellite data on the solar X-ray flux and found that for wavelengths of 8–20 Å, which penetrate to, and are absorbed in, the meteor zone, the solar cycle variation may exceed a factor of 100. A very variable heat source thus exists in the meteor ablation zone.

Wende<sup>14</sup> has investigated the solar cycle variation in the integral, non-flare, solar X-ray flux between 2 and 12 Å, as measured by the spacecrafts Injun 1, Injun 3, Explorer 33 and Explorer 35. Figure 3 compares the monthly means of X-ray flux with the radar rate curve. Although the X-ray data cover only three periods in 1961–68, the data suggest an inverse correlation between meteor rates and solar X-ray flux. Of particular interest is the rather abrupt decrease in the solar X-ray flux observed at the beginning of 1963 simultaneously with the reported worldwide increase in meteor radar rates. The 1963 increase in meteor radar rates might thus reasonably be ascribed to a change in the atmospheric density gradient due to a sudden drop in the solar X-ray flux.

Existing theories of meteor ionisation generally assume an isothermal atmosphere, and do not take into account spatial and temporal variations in temperature in the meteor ablation zone. Therefore no detailed theoretical explanation of the observed long term variations in meteor radar rates and heights is available. Observed changes in radar echo amplitudes of bright, visual meteors<sup>9</sup> are far larger than what one would expect from meteor ionisation theory.

## Self reversal of thermoremanent magnetisation in basalts and global lunar magnetism

RYALL and Ade-Hall have shown experimentally<sup>1</sup> that prolonged heating of pillow basalts in suitable conditions results in the exsolution of a 'daughter' phase from the host titanomagnetite. They suggest that in an applied field the daughter phase acquires a chemical remanent magnetisation (CRM) when it grows to the single domain size and that on cooling, the 'mother' or host phase is subjected to an interaction field from the daughter phase, which, they suggest, could outweigh the effect of the external field and result in a net reversed moment of the sample. They suggest that magneto-static or possibly exchange interaction might be responsible.

By using magnetostatic theory which has already been applied to a simple model of a two-phase titanomagnetite particle—and, on a rather larger scale to the problem of the residual moment of the Moon—it can be shown that a magneto-static interaction can indeed explain their results.

Consider a simple model of a two-phase particle as shown in Fig. 1. The daughter phase is assumed to be spherical, of radius  $a$ , positioned at the centre of a spherical host phase of radius  $b$ . If the relative permeabilities are  $\mu_{1r}$  and  $\mu_{2r}$  respectively, and if the daughter phase carries a CRM of  $M_1$  per unit volume, where  $M_1 = M^*_1 - H_d$  ( $\mu_{1r} - 1$ ), ( $H_d$  is the demagnetising field within phase 1, and  $M^*_1$  is the CRM if  $H_d = 0$ ), then the external moment  $m_e$  is given by<sup>2</sup>

$$m_e D^2 / 4\pi b^3 = 3\sigma \mu_{2r} M^*_1 (\mu_{1r} + 2\mu_{2r})(\mu_{2r} + 2) \quad (1)$$

provided that  $\sigma \ll 1$  where  $\sigma = (a/b)^3$ , and that the permeability of the medium in which the moment is measured ( $\mu_{3r}$ ) is unity. For small values of  $\sigma$ ,  $D = (\mu_{1r} + 2\mu_{2r})(\mu_{2r} + 2)$ . On cooling, the host phase (Fig. 2) will acquire a thermoremanent magnetisation (TRM) in the field produced by the internal dipole (attributable to the CRM) and if  $k$  represents the efficiency of the TRM acquisition process (that is,  $M_{\text{TRM}} = kH$ ) then the external moment, attributable to the spherical shell alone<sup>3</sup> is  $m_i$  where

$$m_i D^2 / 4\pi b^3 = 6k\sigma M_1^* (\mu_{1r} - \mu_{2r}) \quad (2)$$

If  $\mu_{2r} = \sqrt{\mu_{1r}}$ , the external moment attributable to the host phase is thus zero. If the volume of the host particle is multiplied by  $\sim 10^{30}$  the body becomes of planetary dimensions,

Fig. 1 Model of two-phase particle (radii  $a$  and  $b$ ). The inner 'daughter' phase (radius  $a$ ) carries a CRM/ $M_1$  (see text). The moment,  $m_e$ , of the particle is given by equation (1).

Fig. 2 The component of TRM (schematic) acquired by a host phase in field of a daughter phase. The moment,  $m_i$  attributable to this component is given by equation (2). See text for notation.

and if  $\mu_{1r} = \mu_{2r} = 1$ , then  $m_i = 0$ . This result corresponds to that derived for the case of the Moon by Runcorn<sup>4</sup>, who showed that if the outer shell of the Moon were magnetised in the field of an internal dipole which has now disappeared, the present lunar dipole moment should be zero. Since  $\mu_{2r}$ , however, must always exceed unity if a TRM is acquired and probably exceeds  $\mu_{1r}$  in the Moon, a small negative lunar dipole moment should be observed<sup>3</sup>.

Similar theory applied to the component of TRM which the host phase acquires as it cools in the external field  $H_3$  (Fig. 3), enables the following equation to be derived for the external moment  $m_e$ .

$$m_e D^2 / 4\pi b^3 = 3kH_3(\mu_{1r} + 2\mu_{2r})^2 \quad (3)$$

The total moment  $m$  of the two-phase particle is thus the sum of three terms given by equations (1)–(3).

The only negative contribution to the moment comes from the second term, and then it arises only if  $\mu_{2r}^2 > \mu_{1r}$ . This condition is almost certainly fulfilled if, as Ryall and Ade-Hall suggest<sup>1</sup>, the CRM resides in a single domain, daughter phase for which  $\mu_{1r}$  that is,  $(dB/\mu_0 dH) = 1$ .

Fig. 3 The component of TRM (schematic) acquired by a host phase in an external field  $H_3$ . The moment,  $m_e$ , attributable to this component is given by equation (3). See text for notation.

A second condition which must hold if  $m$  is to be negative is that  $|m_i| > m_e$ , and if  $\mu_{2r}$  is assumed to be  $\gg 1$ , then  $\sigma M^*_1 > 2H_3$ . A typical titanomagnetite has a spontaneous magnetisation of the order of  $10^5 \text{ A m}^{-1}$  (100 gauss), so putting  $M^*_1 (= M_1 \text{ for a single domain grain with } \mu_{1r} = 1)$  equal to  $10^5 \text{ A m}^{-1}$  and since  $H_3 \approx 80 \text{ A m}^{-1}$  (1 oersted), then  $\sigma > 1.6 \times 10^{-3}$ , which corresponds to a ratio  $a/b$  of  $\sim 0.1$ . Thus, only about 0.16% by volume of daughter phase is required to produce reversal.

The third condition which is necessary is that  $|m_i| > m_e$ ; thus for  $\mu_{2r} \gg 1$ ,  $k > \mu_{2r}$ . To see whether this condition is reasonable it is necessary to consider how the TRM process operates. Before the host phase cools (assumed multidomain) but while it is still below the Curie point, the induced magnetisation,  $M$ , at any point is  $(\mu_{2r} - 1)H$ , where  $H$  is the local field, and where, if  $\mu_{2r}$  is high,  $M \approx \mu_{2r}H$ . On cooling, this magnetisation becomes blocked in as domain walls become immobilised in local potential wells. On further cooling, the spontaneous magnetisation will change from the value  $M_s(T_B)$  at the blocking temperature  $T_B$ , to  $M_s(T_0)$  at room temperature,  $T_0$ . Thus,  $k = \mu_{2r} M_s(T_0) / M_s(T_B)$ . Since spontaneous magnetisation usually increases on cooling, then  $k > \mu_{2r}$ , and that condition can be satisfied. There are, of necessity, many simplifications in this argument. The factor  $\mu_{2r}$  is assumed to be constant though it will in practice vary with temperature. Each host particle will contain many inclusions of daughter phase which are represented here by a single inclusion which has the same properties as the individual inclusions and a volume equal to the sum of the individual volumes. Spherical symmetry is also assumed. The assumption that  $M_{\text{TRM}} = kH$  will break down near the surface of the single domain inclusion since the local field there will be well above the low field range where a linear dependence is normally found. Nevertheless, provided  $\sigma$  is small, the regions where the nonlinear effects operate will also be of relatively small volume and may possibly be neglected.

In spite of all the simplifications, reverse TRM of the type found by Ryall and Ade-Hall can be explained on magnetostatic theory using the model described here. Before the daughter phase forms, the moment is given by equation (3). As the daughter phase increases in size through the single domain range,  $\sigma$  increases and the second term (equation (2)), which dominates the first (equation (1)), causes a decrease in moment until reversal occurs. Once the daughter phase exceeds the single domain size,  $M^*_1$  decreases and  $\mu_{1r}$  will increase so that the negative contribution will diminish and the moment will revert to normal, in line with experimental observations<sup>1</sup>.

It is interesting that the second term (equation (2)) which governs whether or not reversal occurs is the contribution from that component of remanence in the shell which was produced by the field of the central magnetised inclusion. This would also be the term describing the present lunar global dipole moment were the shell originally magnetised in the field of an ancient dipole which has now disappeared<sup>3</sup>.

## Origin of corundum-normative intrusive and extrusive magmas

MANY intrusive and extrusive calc-alkaline suites show a continuous trend from diopside-normative basic magma to corundum normative acid magmas, that is, with an increasing  $\text{SiO}_2$  content there is an exceptional decrease in the Ca:Al ratio

of the magma. A number of explanations have been proposed for these trends, including secondary alteration, vapour phase transfer, assimilation, crustal remelting, hydrous melting of the upper mantle and the fractional crystallisation of a variety of phases. We demonstrate here that corundum-normative magmas can be produced by the fractional crystallisation of a hornblende amphibole from calc-alkaline magma under moderate water pressure.

A large proportion of granitoid rocks are corundum-normative<sup>1</sup> and Chayes<sup>2</sup> found that 18% of 1,775 andesite analyses he compiled were also corundum-normative. By contrast, rocks of tholeiitic affinity are virtually always diopside-normative, even for the acid differentiates. This difference in normative mineralogy between calc-alkaline and tholeiitic suites has not been adequately explained.

Several calc-alkaline trends, which range from basaltic, through andesitic to dacitic and rhyolitic (gabbroic to ademetilic for intrusive suites) are plotted on Fig. 1, showing the transition from diopside-normative to corundum-normative. All the suites show a systematic trend of decreasing diopside content, eventually becoming corundum-normative with increasing  $\text{SiO}_2$ . The exact value of the  $\text{SiO}_2$  content at which the rocks become corundum-normative varies considerably from about 56% for the Borrowdale volcanics<sup>3</sup> to 70% for the Sierra Nevada batholith<sup>4</sup> and the Cascades volcanics<sup>5</sup>. All the trends, however, appear to be subparallel.

Various models have been proposed for the production of corundum-normative magmas. They include:

**Secondary alteration.** The leaching of alkalis from pumice fragments after eruption could produce corundum-normative compositions<sup>6</sup>. It is, however, unlikely that 18.4% of all andesites<sup>2</sup> could be so affected. It is also remarkable that no tholeiitic suites contain leached compositions. The trends on Fig. 1 are regular. Leaching of alkalis would not be expected to produce as regular an alteration. Alkali leaching from intrusive rocks is very unlikely, and yet they show the same trend as volcanics. We do not accept alkali leaching as a general model.

**Vapour phase transfer.** Interaction of an aqueous vapour phase with magma could remove alkalis<sup>7</sup>. This could, however, only happen once the magma has become water saturated. The evidence does not support the idea that most calc-alkaline suites are water saturated. We do not accept it as the general mechanism for producing corundum-normative magmas.

**Assimilation.** Contamination of magma could produce a corundum-normative product, as has been demonstrated for the Taupo Volcanics, New Zealand<sup>8</sup>. But  $^{87}\text{Sr}/^{86}\text{Sr}$  ratios do not indicate any significant contamination of two of the suites plotted in Fig. 1. The Cascades Volcanics<sup>9</sup> and the Lesser Antilles Suite<sup>10</sup> are not contaminated by crustal material. So we do not favour contamination as a satisfactory way of explaining all corundum-normative magmas.

**Crustal remelting.** Presnall and Bateman<sup>4</sup> appealed to a process of fusion of andesitic crustal material to explain the chemical variation of the Sierra Nevada batholith (although they considered only the granitic component of the rocks). We note that partial melting of andesitic crust leaving an amphibole-rich residue could produce corundum-normative liquids, but corundum-normative magmas are observed where there is no significant continental crust, for instance, in the Lesser Antilles<sup>11</sup>. Thus remelting of continental crust cannot be a generally applicable model.

**Melting of hydrous peridotite.** Kushiro and Yoder<sup>16</sup> have suggested that corundum-normative magmas could be produced by the melting of hydrous peridotite. That model does not, however, explain the continuous trend of compositions from basic to acidic. Furthermore, the model requires unrealistically high geothermal gradients for the mantle. The data were obtained under 10 kbar pressure<sup>12</sup>, and Kushiro<sup>13</sup> subsequently showed that partial melts from a hydrous peridotite were not corundum-normative at 20 kbar. Therefore, corundum-normative magmas would have to be formed at less than 20 kbar (60 km). Probable temperatures at this depth under

Fig. 1. both continental and oceanic crust are too low to partially melt hydrous peridotite.

**Fractional crystallisation.** Kushiro and Yoder<sup>12</sup> also proposed that the fractionation of clinopyroxene could produce a trend from diopside-normative to corundum-normative. The clinopyroxene they synthesised would, however, not produce the trends observed in Fig. 1.

Kuno<sup>14</sup> has suggested that the fractionation of magnetite-rich gabbro could produce the calc-alkaline trend. But there is a thermal divide at low pressure in the plane anorthite-forsterite-quartz<sup>15</sup> such that crystallisation to produce a corundum-normative residue from diopside-normative liquids is not

possible. This is supported by Fitton's finding<sup>3</sup> that clinopyroxene is never observed in corundum-normative compositions. So we do not believe that low-pressure crystallisation can produce corundum-normative liquids.

Green and Ringwood<sup>16</sup> have suggested that garnet pyroxenite fractionation could produce the calc-alkaline trend, but they showed that the liquidus temperatures increased for compositions more siliceous than 61% SiO<sub>2</sub>. In Fig. 1 the trends continue from 50% to over 70% SiO<sub>2</sub>.

A fourth possible fractionation model for the genesis of the calc-alkaline suite has been suggested by Cawthorn and O'Hara<sup>17</sup>. They have suggested that amphibole fractionation may produce the observed chemical variation. We have plotted in the inset of Fig. 1 various amphibole compositions which have been synthesised from basic and intermediate compositions under 5–15 kbar pressure (see ref. 17). These plot on the back projection of the calc-alkaline trends and we suggest the crystallisation of such amphiboles explains these trends satisfactorily. Slight variations in slope of the trends in Fig. 1, may be attributable to different amphibole compositions crystallising at different pressures, or possibly to the coprecipitation of amphibole and plagioclase, which may become important in the most silicic compositions<sup>17</sup>.

Pinwinski and Wyllie<sup>18</sup> have melted a series of corundum-normative granitoid rocks and shown that hornblende is the liquidus phase for most compositions. Thus, amphibole will crystallise from corundum-normative magmas and is capable of producing the characteristic trend of calc-alkaline magmas.

We therefore suggest that amphibole fractionation is the most plausible single model to explain all corundum-normative magmas (although the other models have a limited applicability).

## Argon isotopic evolution of upper mantle

BROWN *et al.*<sup>1</sup> have treated the problem of the history of the argon degassing of the Earth, and claim to demonstrate that the <sup>40</sup>Ar/<sup>36</sup>Ar ratio in the mantle has increased from ~133, 770 Myr ago, to a value that "is at present not greater than the atmospheric ratio (295.5) and is probably a little lower". Their Table 1 and Fig. 1 show the results of K–Ar isochron analyses of several suites of "mantle-derived igneous" samples. We have been unable to reproduce in detail their results from the references they cite, and conclude that the apparent trend in their Fig. 1 is an artefact of data selection and that the source of the

Fig. 1 A K–Ar isochron plot of group IIIA dyke data<sup>2</sup>. The slope and intercept shown are from a regression line fitted to points 5, 22, 23, 24 and 51 (see text), which gives slope =  $0.05274 \pm 0.00052$ ; an age of  $736.7 \pm 6.0$  Myr; intercept ratio =  $298 \pm 34$ .

observed argon has been misidentified. We think the <sup>40</sup>Ar/<sup>36</sup>Ar ratios in the solid earth and the atmosphere have probably increased with time. Theoretical considerations and the available literature both indicate, however, that the <sup>40</sup>Ar/<sup>36</sup>Ar ratio in the solid earth is much higher than the <sup>40</sup>Ar/<sup>36</sup>Ar ratio in the atmosphere.

The apparent trend in Fig. 1 of Brown *et al.*<sup>1</sup> is mainly a function of the oldest datum, number 18, based on seven K–Ar analyses of the "group IIIA dike" samples<sup>2</sup> from the Beartooth mountains. These data are shown in Fig. 1 on a plot of <sup>40</sup>Ar/<sup>36</sup>Ar against <sup>40</sup>K/<sup>36</sup>Ar. A regression<sup>3</sup> of all seven data points using a correlation coefficient of 0.9 yields an age of  $745 \pm 21$  Myr and an ordinate intercept or

Fig. 2 A plot of (<sup>40</sup>Ar/<sup>36</sup>Ar)<sub>i</sub> against age for the suite of samples chosen by Brown *et al.* The dashed line shows the present atmospheric <sup>40</sup>Ar/<sup>36</sup>Ar ratio of 295.5. The error bars shown are one standard deviation (1σ) when the error is larger than the points. The small solid data points are from the calculations of this work. The open data points are those data from Brown *et al.* which differ significantly from ours. Points 15 and 16 of Brown *et al.* have been omitted because the data on which the points are based are not available in the scientific literature and points 2–7 have been omitted for reasons outlined in the text. The large solid data points shown for points 17 and 18 are the values shown in italics in Table 1 and are our best estimates of the trapped gas in these two systems.

\*Data contained in a thesis not available to us.

Our results were obtained using a 1969 York<sup>3</sup> regression program. The correlation between errors in the ordinate and abscissa of the isochron plots was assumed to be zero except as noted in the text. All of the listed errors are 1 s.d. (1σ). The following values were used for the decay constants and abundance of  $^{40}\text{K}$ :  $\lambda_{\text{EC}} = 0.585 \times 10^{-10} \text{ yr}^{-1}$ ,  $\lambda_{\beta} = 4.72 \times 10^{-10} \text{ yr}^{-1}$ ,  $^{40}\text{K}/\text{K} = 1.19 \times 10^{-4} \text{ mol mol}^{-1}$ .

initial  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio of  $252 \pm 133$ . Five of the samples (numbers 5, 22, 23, 24, and 51), however, form a good linear array, and most of the error comes from the two most radiogenic samples (numbers 3 and 30). A regression of the five colinear data yields an age of  $737.7 \pm 6.0$  Myr, and an intercept of  $298 \pm 34$ . We feel that this represents the best estimate of the age and intercept of this suite. Sample 3 contains slightly more radiogenic Sr than the other samples, which may indicate a small amount of crustal contamination. A regression of six samples (omitting number 3) yields an age of  $715 \pm 12$  Myr and an intercept of  $411 \pm 72$ . Brown *et al.*, however, omitted sample 30 and retained sample 3 in their regression, and we have found no objective reason for doing this.

Data from Argyll biotites (ref. 4 and a 1973 Oxford thesis (ref. 30 in Brown *et al.*)) are the source of data points 15, 16 and 17. Because the referenced thesis is unavailable we are unable to check points 15 and 16. We have, however, obtained the unpublished data (J. F. Brown, personal communication; R. J. Pankhurst, personal communication) included with the Argyll data for point 17. The regression of these data yields an age of  $401.1 \pm 6.3$  Myr and an intercept of  $226 \pm 85$ . Since the  $^{39}\text{Ar}$  content in triplicate argon analyses of one of the samples (number 4 in ref. 4) shows almost as much variation, a factor of 1.6, as do all of the data combined, a factor of 1.9, it is clear, however, that these data define mixing lines, not isochrons. The triplicate analyses of sample 4 yield the best defined mixing line with an intercept of  $308 \pm 12$  and an 'age' of  $389.5 \pm 1.0$  Myr. This mixing line is the best estimate of the trapped argon in this system. The system is clearly disturbed, however, since a regression of the data obtained by averaging the replicate analyses of each sample yields an age of  $424.1$  Myr and an impossible intercept of  $-98 \pm 169$ .

Data point 14 is taken from Hayatsu and Carmichael's<sup>5</sup> treatment of data from mineral separates from a pyroxene quartz diorite in the Sierra Nevada of California<sup>6</sup>. The minerals show evidence of alteration<sup>6</sup> and the hornblende datum lies above the line defined by the other minerals (see Fig. 5 of ref. 5). This set of minerals clearly represents a disturbed system. Point 14 also demonstrates graphically the danger of using someone else's K-Ar data for isochron plots. Brown *et al.* apparently assumed, as did Hayatsu and Carmichael<sup>5</sup>, that the column labelled " $^{40}\text{Ar}/^{36}\text{Ar}_{\text{total}}$ " in Table 2 of ref. 6 means radiogenic  $^{40}\text{Ar}$  divided by atmospheric  $^{40}\text{Ar}$  plus radiogenic  $^{40}\text{Ar}$ . Kistler (personal com-

munication) indicates that " $^{40}\text{Ar}_{\text{total}}$ " contains a significant component of  $^{40}\text{Ar}$  from the isotope dilution spike. After correcting for this component we obtain an age of  $117.0 \pm 3.8$  Myr and an intercept of  $266.4 \pm 6.2$  for the quartz diorite minerals—but the hornblende datum still plots off the line.

The rest of the data, points 1–13, have intercepts indistinguishable from the present atmospheric  $^{40}\text{Ar}/^{36}\text{Ar}$  value. Some require comment, however. We calculate higher intercepts and lower ages for points 11 and 12 than do Brown *et al.* The amounts of  $^{39}\text{Ar}$  in replicate analyses involved in points 8 and 10 show wide variations which indicate mixing lines.

Points 3–7 are from analyses of the Auckland volcanic field by McDougall *et al.*<sup>8</sup>. They do draw isochron diagrams but go on to conclude, "these linear arrays of data must be interpreted as indicating that the amount of excess Ar is nearly constant for a given volcano, and that the apparent isochrons are a result of this fact, together with the small variation of K in lavas from a single volcano" (p. 1517).

The data are from mixing lines, not isochrons, and do not belong in a compilation of 'initial'  $^{40}\text{Ar}/^{36}\text{Ar}$  ratios. The clearest case is the data from the Rangitoto volcano. As McDougall *et al.*<sup>8</sup> state, for Rangitoto "the radiocarbon, geological and botanical evidence unequivocally shows that it was active and was probably built in the last 1,000 years" (p. 1485). K-Ar data from Rangitoto define two apparent isochrons and two separate fits are made to one of these<sup>8</sup>, but the 'ages' which accompany these lines are ~500 and 200 times too large.

Point 2 is from work on the SP flow in the San Francisco volcanic field in Arizona<sup>9</sup>. The distribution of  $^{36}\text{Ar}$  through the flow strongly suggests that the  $^{36}\text{Ar}$  came from the atmosphere and not the mantle.

Point 1 is from work on modern surface volcanics<sup>10</sup>. Three samples (out of 27) had  $^{40}\text{Ar}/^{36}\text{Ar}$  ratios less than the atmospheric value, but Krümmenacher<sup>10</sup> demonstrated that these low values were due to mass fractionation effects on argon of atmospheric composition trapped in the lava and "not due to a mixture with primordial argon, that is depleted in  $^{40}\text{Ar}$ ". Brown *et al.* report only three low  $^{40}\text{Ar}/^{36}\text{Ar}$  data as their point 1. Baksi<sup>11</sup> has confirmed the basic observation that mass fractionation is often the dominant process in young volcanic rocks.

Our calculations indicate that Fig. 1 of Brown *et al.* should be replaced by Fig. 2 of this paper. The line shown

in their Fig. 1 is a physical impossibility since it extrapolates to  $-666$  at  $4,500$  Myr. We interpret our Fig. 2 as evidence that most, if not all, of the trapped argon in the samples shown in Table 1 and Fig. 2 is modern atmospheric argon which has been added to the samples during recent weathering and/or laboratory manipulation. There is an additional caveat. Shafiqullah and Damon<sup>12</sup> have recently discussed K/Ar isochrons and conclude that in geologically realistic situations K–Ar isochrons tend to be considerably more complicated than Rb–Sr diagrams, and should be used with great caution.

The best available samples of mantle gases are those trapped in the quenched rims of submarine basalts. These quenched rims of recent submarine pillow lavas contain argon with  $^{40}\text{Ar}/^{36}\text{Ar}$  ratios higher than the present-day atmospheric ratio<sup>13,14</sup>. It has been reported that the elemental ratios of He, Ne, Ar, Kr and Xe in some quenched rims are not atmospheric<sup>15,16</sup>. This is interpreted as evidence that the quenched rims contain primordial rare gases from the mantle. In samples identified as containing mantle gases the  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio varies from 358 to 88,000. Ozima and Kudo<sup>17</sup> have argued that the present mantle  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio is approximately 2,000. We believe that most workers would classify submarine basalts as 'mantle-derived igneous' rocks.

In summary, we can see no evidence for mantle argon with a  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio  $<295.5$ . Data not considered by Brown *et al.* strongly indicate that the  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio in the mantle is  $\geq 295.5$ .

Brown *et al.* assume that "not more than 5% of crustal argon has been released to the atmosphere, and perhaps as little as 1%". They then calculate the amount of  $^{40}\text{Ar}$  accumulated from K in the crust (39% of the Earth's total inventory of K in their model) in  $4,500$  Myr, and release 5% of that  $^{40}\text{Ar}$  in the atmosphere. Brown *et al.* implicitly assume that the entire crust has been in existence for  $4,500$  Myr and has a current average K–Ar age of  $4,412$ – $4,483$  Myr. This assumption violates all of the current theories of continental growth and is completely incompatible with what is known about continental age provinces<sup>19</sup>. While some argon derived from melting and recrystallisation might be trapped in the crust, the young average age of the continental crust,  $\sim 1,100$  Myr, implies that most of the argon is degassed during uplift, weathering, metamorphism (radiogenic  $^{40}\text{Ar}$  is found in natural gases<sup>20</sup>), continental growth, and recycling in subduction zones. The fact that 5% of the crust is now sediments certainly does not mean that only 5% of crustal argon has been released to the atmosphere.

All of the detailed calculations of argon evolution of which we are aware yield mantle  $^{40}\text{Ar}/^{36}\text{Ar}$  ratios higher than the corresponding atmospheric ratio throughout time. No matter what the initial partitioning of Ar was between the solid Earth and atmosphere, the atmosphere has no potassium  $^{40}\text{Ar}$  is produced only in the solid Earth. The  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio in the atmosphere can increase only by the degassing of the solid Earth. Degassing, however, removes both  $^{40}\text{Ar}$  and  $^{36}\text{Ar}$  from the solid Earth. While  $^{40}\text{Ar}$  continues to be produced from the decay of  $^{40}\text{K}$ , there is no mechanism which produces  $^{36}\text{Ar}$  in the solid Earth. Therefore, the  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio in the solid Earth increases faster after a degassing event than it would have if the event had not occurred. Fractionating the potassium into a crust does not change the picture unless one is willing to postulate a differentiation process which removes the potassium while leaving the argon in the mantle.

In conclusion, we agree with the suggestion of Brown *et al.* that it may be possible to measure the time evolution of the  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio in the mantle using K–Ar isochron techniques. If such an evolutionary history can be obtained, it will provide an important boundary condition on petrogenetic and thermal models of the Earth. A similar evolu-

tionary history for the atmosphere may also be obtainable and would be equally important. We have shown, however, that Brown *et al.* have not measured the evolution of the mantle  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio. We predict that if and when such an evolutionary history of the mantle is reconstructed, it will bear no resemblance to that shown in Fig. 1 of Brown *et al.*

WE thank Alexander and Schwartzman (AS)<sup>1</sup> for bringing to light a significant error in data point 18 (Table 1) of our paper<sup>2</sup>. Because of a misinterpretation of a verbal communication from Mueller, we omitted sample 30 in our regression of the data from Baadsgaard and Mueller<sup>3</sup>. We confirm that there is no reason for omitting this sample, and that the data indicate that the non-radiogenic argon present cannot be distinguished from atmospheric contamination. We concur with Alexander and Schwartzman, however, on little else, and consider as still valid the four principal points summarised at the end of our paper<sup>2</sup>: first, the initial  $^{40}\text{Ar}/^{36}\text{Ar}$  ratios of mantle-derived igneous rocks have increased steadily over the past 800 Myr. Second, the present day  $^{40}\text{Ar}/^{36}\text{Ar}$  ratios in the upper mantle and atmosphere are very similar. Third, the majority of argon at present in the atmosphere has been derived from the mantle rather than the crust, and fourth, initial  $^{40}\text{Ar}/^{36}\text{Ar}$  ratios from igneous rocks are potentially more sensitive petrogenetic indicators than strontium or lead isotopes.

Alexander and Schwartzman are unable to reproduce similar ages in their Table 1 for two reasons: first, they consider all  $^{36}\text{Ar}$  to be atmospheric contamination and second, they use a different half-life. We have used the half-life value recommended by Beckinsale and Gale<sup>4</sup>. Thus, as we approach the matter differently, we are likewise unable to reproduce in detail their Table 1 and Fig. 2.

With regard to point 17 of our paper, Argyll biotites, AS prefer to use the intercept of 3 analyses on one sample as the best estimate of the initial ratio. Since line blank is still a major problem in argon isochron analyses, and this sample was not blank corrected, the regression of these

three analyses will give an intercept corresponding to the blank  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio which is atmospheric in origin. Therefore it is not valid for AS to plot this point (17b) on their Fig. 2. Further an age of  $389 \pm 1$  Myr, as suggested by this regression, is too young, since the samples predate, geologically, the granites and lavas of the region which are dated independently by Rb-Sr isochrons at  $425 \pm 5$  Myr ( $t_{1/2} = 5.00 \times 10^{10}$  yr).

Points 3 to 7 refer to McDougall *et al.*'s data<sup>5</sup>. We do not agree that the evidence for the young age of Rangitoto is unequivocal. The samples taken for the radiocarbon ages were covered by tuffs and a basalt flow which represent the latest activity on the volcano. The volcano could have been built up episodically over the past 0.5 Myr. Once again we are only suggesting an alternative interpretation.

A correction of Kistler's data<sup>5</sup> to allow for the spike contribution yields a  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio even lower than we had thought. AS cite petrographic descriptions of the diorite as "evidence of alteration". The cited descriptions, however, indicate the quite pristine nature of these rocks<sup>7</sup>. The mantling of clinopyroxene by hornblende is a normal phase relationship developed during the crystallisation of diorites.

Krummenacher<sup>7</sup> only reported three samples in his Appendix 2 as having a "true"  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio; these are the values we report as our point 1. The rest of his data are not tabulated or corrected in this fashion. Rather than ignoring the possibility of mass fractionation, we agree that it is an important factor which should not be forgotten when analysing young volcanic rocks. What we did say in our paper was that "the possibility of diffusion and fractionation of atmospheric argon into the cooling lava does not seem realistic to us". Krummenacher did not "demonstrate", he merely suggested that fractionation could be the cause of some low initial ratios.

For several of the groups of data AS have repeated the various explanations offered by the investigators (for example the quote by McDougall *et al.*<sup>5</sup> regarding the Auckland data). We have not ignored the explanations given by others for apparently sub-atmospheric  $^{40}\text{Ar}/^{36}\text{Ar}$  ratios, but have tried to offer a single alternative interpretation of the data, given the possibility that these low initial ratios do exist. This possibility has been considerably strengthened by the recent work of Mellor and Mussett<sup>8</sup>. The explanations of others, while perhaps equally valid, do not negate our interpretations. If one can explain low ratios in mantle derived rocks, any higher-than-atmospheric ratios present no problem; they may be explained by higher than average potassium concentration in the source region, extensive outgassing of the source region or xenolithic contamination of the rising magma. For this reason alone, one could justify the selection of low ratios for our model as they represent the closest approach to primordial argon from which mantle argon evolved. This justification is the same as that used in models of the mantle growth of  $^{87}\text{Sr}/^{86}\text{Sr}$  ratios, even though the mechanics and complexities of the models are obviously different. It is not necessary to evolve elaborate mixing or fractionation models to explain low ratios in mantle-derived rocks, and these low ratios are no more 'anomalous' than the high ratios commonly thought of as containing 'excess argon'.

AS perceptively point out that the line shown in our Fig. 1 extrapolates to  $-666$  at 4,500 Myr. Because of this, they claim the line is a physical impossibility, but such a conclusion is hardly valid. The line was intended to be nothing more than an indication of a first-order variation over the time indicated. The rate of growth of  $^{40}\text{Ar}/^{36}\text{Ar}$  ratios in the mantle should not be linear, as it is strongly affected by the outgassing history. If Alexander and Schwartzman applied the same reasoning to their own Fig. 2, they might conclude that the atmospheric  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio 4,500 Myr ago was 295.5.

They make reference to Shafiqullah and Damon's<sup>9</sup> caution against using argon isochrons, this is all very well if they concur with the main postulate of that paper, all  $^{36}\text{Ar}$  measured in an analysis comes from the atmosphere. This postulate was discussed in our paper and rejected in favour of the assumption that a substantial proportion of the  $^{36}\text{Ar}$  measured came from the sample itself. In their very next paragraph AS take the opposite stance and claim that the  $^{40}\text{Ar}/^{36}\text{Ar}$  ratios measured in ocean floor pillow basalts represent the  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio of the mantle source region.

Perhaps we should have explained more fully our estimate of the amount of  $^{40}\text{Ar}$  in the Earth's crust. For the sake of brevity and not anticipating such naiveté from interested readers we did not mention that the value of 4,500 Myr was selected because it is a defensible limiting condition and gives a maximum crustal  $^{40}\text{Ar}$  value. We would be quite content with a smaller value because it is our contention that the crustal contribution to the atmosphere has been minor relative to the mantle contribution.

AS's statement that "the young average age of the continental crust, about 1,100 Myr, implies that most of the argon is degassed during uplift, weathering, metamorphism (radiogenic  $^{40}\text{Ar}$  is found in natural gases), continental growth, and recycling in subduction zones" is fraught with fallacies.

Any such implication would require a comparison of the real age of all crustal material with the respective K-Ar ages. Such a comparison cannot be made, however, for the relevant K-Ar data are minuscule. The only relevant data are from unmetamorphosed rocks, where, in fact, the K-Ar ages are in good agreement with the real ages. The K-Ar data available for the vast metamorphic terranes of the crust are almost entirely from high potassium mineral phases, such as biotite. These minerals are hardly representative of continental crust. There are so little data from metamorphic rocks on the low-potassium phases (for example, plagioclase, pyroxene, and amphiboles), where 'excess argon' is common, that it is premature to attempt to evaluate the average K-Ar age of the continental crust.

Argon is not degassed during uplift. We are startled that Alexander and Schwartzman think otherwise. The evidence is too voluminous and familiar to geologists to cite here, but a large number of studies have shown that uplift results in argon retention.

Some argon is released to the atmosphere by weathering, but most of this would be taken into account in our consideration of sedimentary rocks. In fact it is possible that the retention of Ar by detrital material has led us to overestimate the significance of this surface process.

Metamorphism takes place at depth and the argon becomes mobile, at least on the whole-rock scale, but it cannot pass upwards through the cold capping rocks, except, perhaps along major fissures. If this were not the case, then the identification of excess argon in low potassium phases in metamorphic rocks would be extremely rare.

The fact that "radiogenic  $^{40}\text{Ar}$  is found in natural gases" has no bearing on this matter. Alexander and Schwartzman refer to work done by Moorbath *et al.* in Iceland. It is perplexing to wonder what relationship they think this has to outgassing and metamorphism of continental crust.

There is absolutely no evidence that argon is outgassed during "continental growth and recycling in subduction zones". On the contrary, isotopic studies indicate the insignificant role of older continental material in the generation of new continental crust and also that there is either no recycling, or it is a process which has escaped detection.

One of the major differences between our models and the thesis of Alexander and Schwartzman is that they consider the whole Earth as being equally capable of degassing,

whereas we consider the upper mantle and the crust as separate systems with only the upper mantle having the capability for major outgassing through volcanism.

We believe that low initial  $^{40}\text{Ar}/^{36}\text{Ar}$  ratios do exist in mantle-derived rocks and that these ratios reflect a mantle, or region of the mantle, which had a  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio of  $<295.5$  when the rocks formed.

If the mantle does contain a source of argon which, not long ago, had a  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio less than the present-day atmospheric value, then it is relatively easy to explain any higher initial ratios observed. The real difficulty is encountered when one attempts to explain the derivation of low ratios from a mantle with high  $^{40}\text{Ar}/^{36}\text{Ar}$  ratios. Alexander and Schwartzman recognise this difficulty, but can circumvent it by not accepting the existence of initial  $^{40}\text{Ar}/^{36}\text{Ar}$  ratios less than the present-day atmosphere. Our interpretation has its own difficulties, but none so severe as indicated by AS. We have tried to account for less than atmospheric  $^{40}\text{Ar}/^{36}\text{Ar}$  ratios in the mantle. The model promoted by Alexander and Schwartzman cannot account for, and in fact denies, the possibility of such ratios. It must distress AS somewhat to know that  $^{40}\text{Ar}/^{36}\text{Ar}$  ratios significantly less than atmospheric have been directly measured from the Golovnin volcano (Kurile Islands) on two separate occasions by different researchers<sup>10,11</sup>. Also there is now an example of an extremely low  $^{40}\text{Ar}/^{36}\text{Ar}$  initial ratio in the 625-Myr-old Franklin diabase dykes<sup>12</sup>, and data from the 60-Myr Antrim basalts<sup>8</sup> indicate lower than atmospheric  $^{40}\text{Ar}/^{36}\text{Ar}$  ratios in agreement with our model.

The real contention thus lies in whether or not mantle-derived rocks can contain  $^{40}\text{Ar}/^{36}\text{Ar}$  ratios of less than that of the present-day atmosphere. Future research will resolve this contention.

## Temperature dependence of the anomalous specific heat of glasses and amorphous solids

THE low temperature specific heat of glasses and amorphous solids is characterised by an anomalous linear variation with temperature<sup>1–6</sup>. Of the proposed theoretical explanations (reviewed by Leadbetter<sup>7</sup>), the most favoured attributes this anomaly to localised two-level systems<sup>8–9</sup> or to low frequency vibrations of single atoms or molecules trapped in cavities<sup>10,11</sup>. It is difficult, however, to conceive of a level-splitting mechanism that would be sufficiently general to explain the apparent universality of the anomaly. Moreover, several impurities that could have produced two-level systems have now been eliminated as possible candidates<sup>12,13</sup>. An explanation based on low frequency vibrations of atoms or molecules in cavities rests on two *ad hoc* assumptions about the size and distribution of the cavities, and Stephens *et al.*<sup>5</sup> argue that to account for the

experimental results, these assumptions seem to be physically implausible.

Experimental evidence implies that the amorphous state may be thought of simply as the crystalline state saturated with the most favoured dislocations<sup>14</sup>. This accounts for the densities of the crystalline and the amorphous state being very similar. Various aspects of the mechanical behaviour of metallic glasses have been discussed fruitfully in terms of dislocations and their movements<sup>15–19</sup>, and we show here that this also accounts for the enhanced specific heat of glasses and for their anomalous linear temperature dependence.

Crystal defects can affect the specific heat of a solid by changes in the distribution of vibrational frequencies<sup>20</sup>. Further, extended defects or dislocations can produce low frequency vibrations which are effective at low temperatures. At sufficiently low temperatures ( $\sim 1$  K) it is not unreasonable to expect that dislocations will be pinned either by impurities or at their crossing points. Granato<sup>20</sup> analysed the pinned-dislocation contribution to the specific heat per mole,  $C_v$ , and found that at low temperature

$$C_v = \frac{p\pi^2}{3} \frac{\Lambda a^2}{Z} \frac{Nk}{\theta} T \quad (1)$$

where  $p = v_o/C$  ( $v_o$  is the velocity of sound in the perfect lattice and  $C$  is given by the relation  $C = (G/\rho)^{1/2}$  where  $G$  is the shear modulus and  $\rho$  the density),  $\Lambda$  is the dislocation density,  $a$  the lattice constant,  $Z$  the number of atoms per unit cell,  $N$  the number of atoms per mole, and  $\theta$  the Debye temperature. Thus, for a given solid, the contribution of the vibrations of pinned dislocations to the specific heat is of the observed form. It is interesting to note that equation (1) depends on dislocations only through their density, and that the distribution of dislocation lengths is irrelevant. One also notes that neither the Burgers vector nor its distribution enters the expression. At  $\sim 1$  K the dislocation contribution to the specific heat may be of the same order of magnitude as that of the lattice. For heavily cold-worked aluminium at 1 K this contribution was found to be 20% of the total specific heat and a larger fraction at lower temperatures<sup>20</sup>.

In seeking to obtain quantitative corroboration of these ideas one must contend with the fact that experimental data for glasses invariably refer to multi-element compositions, so average values must be inserted in equation (1). Golding, Bagley and Hsu<sup>21</sup> find that for  $\text{Pd}_{78}\text{Si}_{16}\text{Cu}_6$  the anomalous linear region gives  $C_v/T = 1.3 \times 10^4$  erg mol<sup>-1</sup> K<sup>-2</sup>. Using the weighted averages  $a = 3.8 \times 10^{-8}$  cm,  $\rho = 10.3$  g cm<sup>-3</sup>,  $G = 8 \times 10^{11}$  dyne cm<sup>-2</sup>,  $\theta = 344$  K,  $Z = 4$ , and noting (with Granato<sup>20</sup>) that  $v_o = ak\theta/\pi\hbar$ , one finds from equation (1) that  $C_v/T = 5.6 \times 10^{-10} \Lambda$  erg mole<sup>-1</sup> K<sup>-2</sup>. The saturation condition corresponds to the situation in which adjacent dislocation cores are contiguous, which implies that  $\Lambda = (r_c^2/3)/2$ , where  $r_c$  is the core radius. For a typical metal, such as copper, it has been found that the core radius is  $\sim 3.6$  Burgers vectors<sup>22</sup>. The most likely shear dislocation in close-packed structures is the Shockley partial with a Burgers vector of  $0.41a$ . Thus saturation corresponds to  $\Lambda = 9.2 \times 10^{13}$  cm<sup>-2</sup>, giving finally  $C_v/T = 5.2 \times 10^4$  erg mol<sup>-1</sup> K<sup>-2</sup>. In view of the difficulty involved with using average values the agreement with the result of Golding *et al.* is quite good.

Because core radii are invariably a few Å, the saturation dislocation density is roughly constant so it is not surprising that the anomalous specific heat contribution for different substances does not vary greatly<sup>2,6</sup>. Further, the scattering of phonons by dislocations implies that the thermal conductivity, if this type of scattering is dominant, would be  $\propto T^2$ . It is experimentally observed that the temperature exponent of the thermal conductivity for non-crystalline solids varies between 1.8 and 2.0<sup>2,6,23</sup>. (It should be noted that although Lasjaunias *et al.*<sup>23</sup> found that the thermal conductivity of vitreous  $\text{B}_2\text{O}_3$  between 0.1 and 1.3 K varies as  $T^{1.9}$  the excess specific heat contribution seemed to vary as  $T^{1.46}$  between 60 mK and 0.6 K. The reason for this behaviour is not clear to us.) In the limit as  $T \rightarrow 0$  equation (1)

is invalid, and Granato<sup>20</sup> gives an expression

$$C_v = \frac{\Lambda}{L} \frac{a^3}{Z} Nk \left( \frac{\hbar \omega_0}{kT} \right)^2 \exp(-\hbar \omega_0/kT) \quad (2)$$

which goes exponentially to zero at very low temperatures ( $\omega_0$  corresponding to the lowest vibrational mode). This indicates a method of testing these ideas.

## Cementite structure for iron sulphide, Fe<sub>3</sub>S

IN our studies on the growth of iron sulphides in an inert gas, we synthesised a new crystal form of iron sulphide having a cementite-type structure. The method was the following: a fine powder of synthetic troilite (Fe<sub>1.0</sub>S) was flash evaporated in 99.99% pure argon gas at 100 mmHg, and passed into a vacuum chamber initially at a pressure of 10<sup>-6</sup> mmHg. A thin film was obtained on some water-cooled microgrids 10 mm from the evaporation source (1,900 °C) and was examined in a Hitachi HU-11D electron microscope equipped with the model HXA-1 electron probe microanalyser (with mica as dispersing crystal).

The intensities and lattice spacings as observed and calculated are listed in Table 1. The pattern can be indexed on the basis of an orthorhombic unit cell with  $a=4.56$  Å,  $b=5.09$  Å,  $c=6.70$  Å.

Cementite<sup>1</sup>, Fe<sub>3</sub>C, space group Pbnm, has an orthorhombic unit cell with  $a=4.523$  Å,  $b=5.088$  Å and  $c=6.743$  Å. On the other hand, vanadium subsulphide<sup>2</sup> β-V<sub>3</sub>S is known to have a tetragonal unit cell (P<sub>4</sub>/nbc) with  $a=9.381$  Å and  $c=4.663$  Å. From the better agreement with the lattice constants of the former, the new crystal probably has the cementite structure. The electron diffraction data for the iron sulphide yield no further information, since there are too many overlapping and coinciding peaks.

The chemical composition of the thin film was established roughly by X-ray emission spectra, using 2C-type pyrrhotite film (FeS) as a standard. A film was prepared by the flash evaporation of the same starting material (Fe<sub>1.0</sub>S) in argon at 35 mmHg, and its chemical composition was determined by the presence of the  $d(100)=5.16$  Å line of the 2C-type superstructure. The intensity measurements of the Kα lines of Fe and S reveal that the new phase is very much richer in iron than sulphur, and the composition falls between Fe<sub>2.5</sub>S and Fe<sub>2.8</sub>S.

$$a = 4.56 \text{ Å}, b = 5.09 \text{ Å}, c = 6.70 \text{ Å}.$$

It is postulated that the film-like deposits form at 100 mmHg because of the high density of vapour in the narrow condensation region which comprises different supersaturation zones. This is confirmed by the fact that thin films composed of 2C-type pyrrhotite ( $\text{FeS}$ ), marcasite and pyrite ( $\text{FeS}_2$ ) were obtained near the evaporation source except for a few regions where the iron-rich sulphide was the single phase.

There are two restrictions on the conditions of film formation of the iron sulphide in this experiment: first, the only position at which the thin film could be obtained was at a distance of 7–15 mm from the evaporation source. Further away, the subsequent growth leads to the formation of iron sulphide smoke particles, until they aggregate into a chain of composition  $\text{Fe}_{1-x}\text{S}$ . Second, at lower pressures, 5 and 35 mmHg, the thin film obtained at the same position was not the cementite-type iron sulphide, but only 2C-type pyrrhotite used above as the standard sample. Further details will be published elsewhere.

We thank T. Hatano for discussions and K. Sakaguchi for his assistance.

## Growth rates of freely falling ice crystals

THE only available set of laboratory measurements of mass growth rates of freely falling ice crystals, as a function of both time and temperature, used growth times < 50 s (ref. 1). We report here results of laboratory measurements on freely falling ice crystals (average mass,  $\bar{m}$ ) grown in simulated cloud conditions, as a function of temperature for growth times of  $60 \pm 3$  and  $100 \pm 5$  s, and from these we have calculated the corresponding mass growth rates.

We wished to simulate the growth processes occurring in natural clouds, and therefore the measured ice crystals were produced in, and then grew while falling freely

Fig. 1 Average mass of freely falling ice crystals as a function of temperature for growth times of 1,  $60 \pm 3$  s and 2,  $100 \pm 5$  s.

Fig. 2 Average mass growth rate of freely falling ice crystals as a function of temperature in the time range 60–100 s. calculated from: this work (●); Mason<sup>9</sup> (△) and Ryan *et al.*<sup>10</sup> (○)

through, fogs of supercooled water droplets with size spectra and concentrations similar to those of many rain clouds. The ratio of droplets to ice crystals was always > 8 : 1.

Ice growth was initiated by the rotation of a metal rod, cooled with liquid air, which locally seeded the supercooled fog with tiny ice crystals. The settling ice crystals were sampled by collecting them on a cooled glass slide coated by a layer of highly viscous silicone oil (DC 200/1,000). Each of the samples comprised ~ 150 crystals.

The average mass values of the samples were calculated from the measured diameters of the water droplets resulting from melting the collected ice crystals. Details of the experimental system and procedure are described elsewhere<sup>2</sup>.

Figure 1 shows the temperature-dependent average mass of ice crystals, sampled at  $60 \pm 3$  and  $100 \pm 5$  s after seeding, and Fig. 2 shows their calculated temperature-dependent average mass growth rate in the time range 60–100 s.

It is obvious from Fig. 2 that, first, there are peaks in the growth rate at ~ -5.5 and -18 °C, as have been found previously<sup>1,3,4</sup>; second, the maximum at about -5.5 °C is similar to the behaviour of the basal linear growth rate<sup>5</sup>, basal mean migration distance<sup>6</sup> and basal step propagation velocity<sup>7,8</sup>; and third, the few growth rates for the range 60–100 s, calculated from experiments by Mason<sup>9</sup> and Ryan *et al.*<sup>10</sup> are in good agreement with our results.

## 'Braille' reading by a blind volunteer by visual cortex stimulation

THE possibility of developing functional visual prostheses was supported by the pioneering case of Brindley and Lewin<sup>1,2</sup> and confirmed by our subsequent report on two other blind patients<sup>3</sup>.

Although much work remains to be done on engineering design<sup>4,5</sup> and on minimising the effects of continuous chronic electrical stimulation of the brain<sup>6,7</sup>, the most fundamental question remains the demonstration of useful information transfer by cortical stimulation.

We therefore report preliminary experiments in which a blind volunteer was, without practice, able to read 'braille' transmitted by cortical phosphenes at 30 letters min<sup>-1</sup> (much faster than he could read tactile braille). This patient was also able to use a TV camera to detect horizontal and vertical lines. These experiments with dynamically changing pattern presentation are the first demonstration of potentially useful information transfer by cortical stimulation.

Similar attempts to transmit 'cortical braille' to Brindley's second patient<sup>8</sup> were hampered by large, anomalous phosphenes which limited reading to 8.5 characters min<sup>-1</sup>, much slower than the patient could read tactile braille. It should, however, be emphasised that as yet we regard 'cortical braille' primarily as a technique to begin investigation of dynamic pattern presentation, rather than as a basis for clinically useful prostheses.

Our previous experiments<sup>3,9</sup> used temporary electrode arrays removed a few days postoperatively, but the time limitations of this approach are a serious drawback. Consequently, we designed a chronic implant (Fig. 1) by modifying our ribbon cable electrodes to connect with a special percutaneous pedestal<sup>10</sup> developed in the course of our parallel programme on auditory prostheses.

The volunteer, a 33-yr-old man, was blinded ten years ago by gunshot. He had been associated with the project for several years and his fully informed consent had been obtained<sup>3</sup>. Surgical techniques and postoperative instrumentation were similar to those described earlier<sup>3</sup>, with the addition of a camera based on a 100×100 charge-coupled phototransistor array interfaced with the computer system.

Most stimulation has been conducted with 0.1–1.0-s trains of constant current, symmetrical, biphasic square pulses, coupled through 0.47  $\mu$ F series capacitors, typically of zero to peak amplitude 0.5–3.0 mA, of 0.25/0.25 ms duration (–/+), repeated at 50 Hz. All simultaneous stimulation of multiple electrodes involved individual amplitude adjustments to a constant multiple (typically 1.25) of threshold, and all trains were interlaced typically with 1.0-ms intervals between pulses delivered to different electrodes in numerical order.

Sixty of the 64 electrodes have continuous connecting wires. All produce point phosphenes (some are multiples) at thresholds ranging from 0.8–4.0 mA zero to peak (1.7 mA average with a median of 1.4). These thresholds fluctuated during the postoperative consolidation period, stabilising during the fourth week. They do not seem affected by the limited, intermittent, stimulation involved in our experiments to date. As expected<sup>9</sup> there are no significant differences in phosphene appearance or thresholds based on electrode area.

Electrode 'impedances' are complex and nonlinear. For 0.25/0.25 ms duration (–/+) pulses, 5.2–21.5 V peak to peak (average 8.5; median 8.4) are necessary to force 3.0 mA peak to peak. There is no clear correlation of 'impedance' with either threshold or electrode area.

A detailed map (Fig. 2) of the relative position of each phosphene in the visual field was prepared under computer control<sup>3</sup> with adjustments for absolute distances between

**Fig. 1** Array of 64 platinum electrodes in a Teflon matrix. They are hexagonally packed on nominal 3-mm centres, in the subdural space on the right medial occipital cortex. 12 electrodes are 2 mm<sup>2</sup> in area and the remainder 1 mm<sup>2</sup>. In this X ray they are numbered in horizontal rows (number 1 in the upper right, number 8 in the upper left, number 57 in the lower right, and number 64 in the lower left). The integral platinum connecting wires are individually insulated with Teflon and form a small cable which passes through the skull and folds beneath temporo-occipital periosteum. The wires terminate in a special high density connector inserted in a percutaneous Pyrolite carbon pedestal, attached to the cranial vault with special bone screws.

phosphenes based on a manually prepared map.

As previously reported<sup>3</sup> simple letters and patterns can be recognised easily, although this is hampered by interactions which often occur between phosphenes which are neighbours in visual space (regardless of the position of the corresponding electrodes in the array). The number and spatial distribution of phosphenes is inadequate for presentation of 26 ordinary letters. Consequently, as indicated in Fig. 2, six non-interacting phosphenes were selected to form a 'braille cell'.

Using randomised alphabets, presented as 0.5-s trains of cortical stimulation at intervals controlled by the patient's response, he averaged 19 (17–20) correct responses out of 26 letters (73%) over an average period of 47 (44–56) s. Changing the method of presentation slightly so that each letter was represented by a 0.5-s train at regular 2.0-s intervals, the patient averaged 85% correct responses in three trials with similar random alphabets.

The results with 'cortical braille' contrast sharply with similar experiments using tactile braille scanned at the same rate. Random alphabets were punched on file cards to optimise tactile sensation, and the patient permitted to examine each letter for 2 s. A tone indicated a shift to the next letter, and in these conditions the patient averaged only 28% (23–35%) correct responses in each of three trials.

We then changed to sentence presentation using 'cortical braille' at a rate of 30 characters min<sup>-1</sup> (0.5 s trains delivered every 2 s, with a 4-s pause between words). The initial presentations (selected from a braille reading test) and responses were as follows: (1) "When the crow went into"

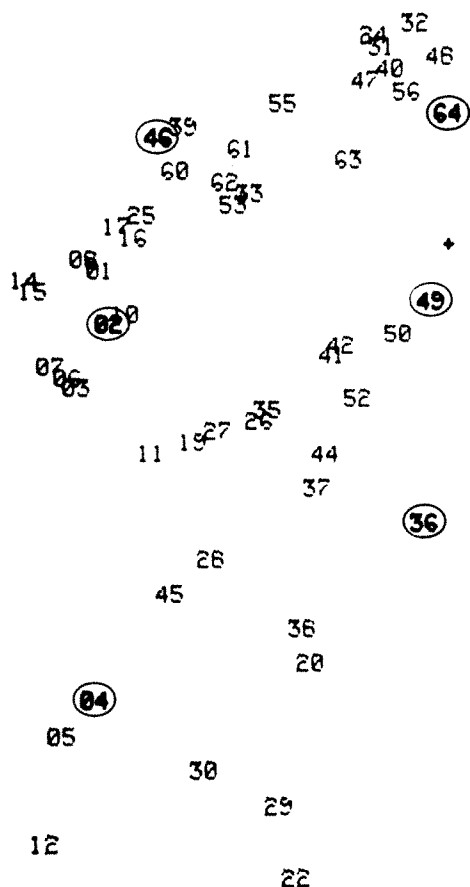

(54 s) read as "... crow went n to". (2) "He had a cat and ball" (52 s) read as "He his cat and ball". (In this case he actually spelled the word "has" properly out loud but called it "his".)

The patient who has a high-school education is a very poor braille reader, averaging about 1 word min<sup>-1</sup> on high school level, grade II (contracted) braille; consequently, he rarely uses tactile braille. He believes, and we concur, that he will become considerably faster at 'cortical braille' with practice, particularly when he can control the rate of presentation through a modified tablet now being interfaced with the computer. Preliminary experiments with kinaesthetic feedback were conducted using the IC camera interfaced with the computer system (0.5-s trains with a maximum of 8 electrodes per frame). Although complicated by phosphene interaction, the patient could distinguish horizontal and vertical strips of 1 inch wide white tape on a black background, and further experiments are now in progress.

Experiments with 'cortical braille' and the camera emphasise the need for interframe delays, particularly when using very short trains (for example, 125-ms trains repeated at 250-ms intervals). At frame rates faster than 4 s<sup>-1</sup>, presentations tend to blur, regardless of the patient's ability to recognise and retain individual characters. From the patient's description, we believe that such blurring results from short duration phosphene persistence, compounded

**Fig. 2** Cathode ray tube map of phosphene positions in visual space. The phosphene produced by electrode number 22 is about 22° from the fixation point marked by (+). As expected<sup>1-3,9</sup> there are many discrepancies from the classical retinotopic map. For example, electrodes far from the occipital pole produce central phosphenes. Adjacent electrodes (for example numbers 30, 31 and 32) may produce widely spaced phosphenes, perhaps due to intervening fissures. Adjacent phosphenes, however, produced by distant electrodes (for example numbers 1 and 16) are more difficult to explain. The circled bold numbers indicate the 6 phosphenes forming the 'braille cell' (electrodes number 46, 2, 4, 64, 49 and 36).

by the intrinsic phosphene flicker. Further experiments on both of these phenomena are also in progress.

We thank the patient and his family; we also thank D. Eddington, M. Womack, G. Dulmage, and J. Crandall and others for assistance. The research was supported by the Max C. Fleischmann Foundation, William Volker Fund, William Randolph Hearst Foundation, and other contributors through the Artificial Organs Development Fund of the University of Utah. Computer systems donated by S. Olsen in conjunction with Digital Equipment Corporation, and the CCD camera chip by Fairchild Semiconductors. Assistance in pedestal and connector fabrication donated by ITT Cannon Corporation and General Atomic Corporation.

## Ethylene-induced volatile inhibitors causing soil fungistasis

THE phenomenon of soil fungistasis<sup>1-3</sup>, a term introduced by Dobbs and Hinson<sup>1</sup> to describe the failure of almost any fungus propagule to germinate in the upper layer of non-amended natural or cultivated soil, has been attributed to volatile inhibitors. Evidence implicating volatile unsaturated hydrocarbons was first obtained from the observation that when soil blocks are incubated in closed containers over either silver nitrate or mercuric perchlorate solutions, they exhibit reduced fungistatic activity against conidia of *Arthrobotrys oligospora*<sup>2</sup>.

To test the hypothesis that ethylene is the main inhibitor involved in soil fungistasis<sup>3</sup>, nutrient-free water agar disks 2 mm thick (Special Agar Noble, Difco), carrying conidia of *A. oligospora* were incubated at 22 °C in atmospheres containing up to 50% (v/v) ethylene (Ethylene CP Calibration Mixture, Commonwealth Industrial Gases). Contrary to what should have been expected if ethylene had any fungistatic activity, conidia germination in all cases proceeded unrestricted, and equalled that of the control series in ethylene-free atmospheres. The use of nutrient-free agar renders unlikely the argument that results obtained in pure culture cannot be extrapolated to unsterilised soil because the fungistatic action can be overridden by nutrients<sup>4</sup>. This

becomes even more apparent in view of the following tests. Using a modification of the Romine and Baker soil emanation technique<sup>7</sup>, agar disks, similar to the ones used in the ethylene bioassays, were laid in disposable Petri dish halves (3.5 cm diameter). These were placed inverted on the surface of 100-g soil samples. A glass vial (10 ml), containing a folded piece of glass-fibre paper and either silver nitrate solution (2.5% w/v) or water, was included in the headspace of soil in each Petri dish. The soils, in this and subsequent experiments, were collected on the day of use and sieved to 0.2 cm while still moist. After 3 d incubation at 23 °C, the fungistatic activity of the agar disks was assessed by seeding, on their lower surface, conidia of either *Penicillium chrysogenum* or *P. italicum* and counting the percentage germination after 18 h further incubation in the same conditions. The experiment was repeated a number of times in triplicate using originally Irish (clay loam, pH 6.6, University College, Dublin) and subsequently Tasmanian (sandy clay loam, pH 5.5, Hobart area) soils. On all occasions the results were of comparable order and showed that the agar disks of the silver nitrate series were less fungistatic compared with controls. Typical results are presented in Table 1. Kouyeas, in the Agricultural College of Athens, using a similar experimental arrangement and four soils from southern Greece (pH 7.6–7.9), obtained comparable results with eight different fungal species<sup>8</sup>.

The fact that agar disks acquire fungistatic properties when exposed to volatile emanations from soil, but not when incubated in the presence of ethylene, leaves no doubt as to the ineffectiveness of the latter as a spore germination inhibitor. Examination of the electronic spectra of water condensates collected from soil headspace revealed, however, that ethylene-like substances were present in the soil gaseous emanations.

In these experiments, an all-glass cold finger condenser, with a small vial suspended from its lower end, was suspended over 500-g soil samples held in conical flasks (2 l). During the experiment the soil temperature was kept at 25 °C whereas that of the water circulating in the condenser was about 10 °C. An incubation period of about 24 h was usually sufficient for the collection of 5–10 ml water condensate in the receiver vial, beneath the condenser.

Water condensates from both Irish and Tasmanian soils had a greater  $A_{196}$  than distilled water. By adding dropwise a freshly prepared bromine water solution into the sample cell only, an absorption band emerged in the region of 165 nm, the intensity of which increased with further addition of bromine.

Trimethylamine or formic acid ( $1 \text{ mg l}^{-1}$ ) could account for the  $A_{196}$ , but neither showed any response to bromine treatment; and when they were neutralised both failed to inhibit spore germination. Water saturated with ethylene or solutions of other compounds containing an ethylene double bond, when treated with bromine, gave an absorption curve similar to the one that was given by soil water condensates under the same treatment (Fig. 1), indicating the presence of ethylene-like substances among the soil gaseous emanations.

Since ethylene itself has no inhibitory effect on spore germination, however, Smith's observation, that soil fungistasis is enhanced in the presence of ethylene<sup>3,9</sup>, leads to the alternative hypothesis that ethylene might trigger or accele-

Fig. 1 Absorption spectra of water condensates of soil headspace (a), water saturated with ethylene (b), allyl alcohol (c) and acrylic acid (d).  $a^*$ – $d^*$ , Same as above after treatment with bromine.

rate the process by which the inhibitor(s) is produced. Water condensates were collected, as described above, from soil samples (1 kg fresh weight) which had been pre-incubated for 3 d in atmospheres of air only or air supplemented with 1% ethylene. After collection, the water condensates were transferred to glass vials, which were sealed with rubber septa and placed in a 60 °C water bath. Gas samples (2 ml) were withdrawn from the headspace of each vial and analysed in a Pye Unicam 104 Gas Chromatograph with a  $1.60 \times 0.003 \text{ m}$  column packed with 5% Carbowax 20M on Gas Chrom Q (80/100 mesh), 60 °C,  $\text{N}_2$  carrier gas and  $\text{H}_2$  flame ionisation. Condensates from the ethylene-treated soil yielded, apart from a peak attributable to ethylene, several others with poor resolution and one with retention time similar to allyl alcohol (approximately 5.5 min). Characteristically, no peak was registered when samples of water condensates from air-treated soil were used. Incubation of soil in presence of ethylene thus resulted in the production of other volatile substances; although they are awaiting identification and assessment of their significance, formation of allyl alcohol alone may account for the enhancement of fungistatic activity in soils treated with ethylene as the following microdiffusion germination tests indicate.

Although acrylic acid was not detected, it was included in the bioassays because of its close similarity to allyl alcohol, the fact that Shmuk (cited in ref. 10) had included this acid in a list of organic substances isolated from soil by numerous investigators, and its identification with the factor responsible for the antibacterial properties of phytoplankton and seaweeds<sup>11–14</sup>.

Bioassays were carried out using a microdiffusion system designed to simulate the conditions of the spore germination tests on soil blocks<sup>2</sup> and those of the agar disk technique above. Films (1 mm thick) of nutrient-free agar carrying conidia of *A. oligospora* were incubated over solutions of either allyl alcohol or acrylic acid in containers similar to Conway's microdiffusion dishes (3.4 cm diameter, 2 cm deep; central compartment, 1.4 cm diameter, 1 cm deep). Aliquots (5 ml) of the compound under test were placed in the outer compartment of the dishes whereas the inner compartment received 1 ml silver nitrate solution (2% w/v) and a small pleated piece of glass-fibre paper to increase the absorbing capacity of the solution.

Table 2 shows that the diffusing vapours from both allyl alcohol and acrylic acid solutions were fungistatic and that the presence of silver nitrate resulted in a dramatic reduction of their inhibitory effect. The fact that allyl alcohol seems more effective (quantitatively) than acrylic acid

Table 1 Percentage spore germination on nutrient-free agar disks pre-exposed to volatile emanations from soil, in the presence or absence of silver nitrate solution

Soils	Test organisms	Silver nitrate solution	
		Present	Absent
Irish	<i>P. chrysogenum</i>	$62 \pm 5.0$	$44 \pm 3.5$
Tasmanian	<i>P. italicum</i>	$80 \pm 5.3$	$52 \pm 6.2$

**Table 2** Percentage germination of *A. oligospora* conidia in micro-diffusion tests of allyl alcohol and acrylic acid in presence or absence of silver nitrate solution

Test compound	Silver nitrate solution	
	Present	Absent
Water (Control)	95 ± 2.1	96 ± 1.2
Allyl alcohol (4 p.p.m.)	46 ± 4.6	13 ± 0.8
Acrylic acid (1,000 p.p.m.)	77 ± 3.4	7 ± 2.0

should not be considered as evidence lessening the possible ecological significance of acrylic acid. The microdiffusion system used does not give a direct measure of the potency of the inhibitors but reflects the balance between the rate of diffusion and subsequent accumulation of the inhibitor in the agar films and the rapidity with which spores are germinating. It is, therefore, the relatively high speed with which the conidia of *A. oligospora* germinate and presumably, the low diffusion rate of vapours of acrylic acid, together with a moderate activity, that result in an underestimation of its effectiveness as a fungistatic agent. Thus, when agar films were immersed for a few minutes in acrylic acid solutions and used for germination tests, the effective dose for 50% inhibition was reduced to only 40 p.p.m.

Presence of nutrients counteract the soil fungistatic activity. Similarly, the inhibitory effect of both allyl alcohol and acrylic acid increases progressively with the decrease of the nutrient status of the spores. Note that both the above compounds, within a certain concentration range, depending on the fungus species and the level of nutrients, do not impair the viability of the spores for a considerable period of time (C.B., unpublished).

Brian *et al.*<sup>15,16</sup> have studied the fungistatic activity of a number of ethylene-like compounds and indicated that fungistatic activity is related to the tendency of the substituent groups to withdraw electrons from the double bond<sup>14,15</sup>. This proposition readily explains the contrast in activity between ethylene and allyl alcohol and acrylic acid. The activity of the latter is probably restrained because of the low permeation of cells by organic acids.

My results are in accord with Smith's observation that ethylene causes soil fungistasis<sup>9</sup>, except that the main inhibitor of spore germination is not ethylene but the ethylene-induced and tentatively identified allyl alcohol and perhaps other products. Smith's concept of the oxygen-ethylene cycle<sup>9</sup> may, therefore, represent only part of a more complex system awaiting elaboration.

## Rhythmic oscillations of phytochrome and its pelletability in *Cucurbita pepo* L.

MANY reactions of plants (such as flower initiation, growth and chlorophyll synthesis) show a rhythmically changing sensitivity to light<sup>1</sup>. According to Bünning's hypothesis, the photoperiodic reactions are determined by the interaction between an endogenous rhythm and phytochrome: both components are essential for a photoperiodic response. The endogenous rhythm determines the changing sensitivity of the plant to  $P_{fr}$ , the physiologically active form of phytochrome. These characteristic changes in the sensitivity of the system towards light are probably not attributable to different  $P_r$  molecules. On the basis of the theory that the binding of  $P_r$  to a membrane is the primary reaction of phytochrome, it has been suggested<sup>2</sup> that such sensitivity changes could be achieved by varying the interaction of phytochrome molecules with their receptor sites. We have investigated the association of phytochrome with pelletable structures<sup>3,4</sup> and found that after a 12-h white light induction the total amount of phytochrome and its pelletability oscillate in the dark with frequency periods of 24, 12 and 6 h.

For routine preparations of particulate fractions, pre-chilled tissue—cotyledons or hooks of Squash (*Cucurbita pepo* L., cv. Black Beauty)—were chopped with a razor blade and homogenised with a mortar and pestle in extraction medium. In all experiments the medium-tissue ratio was 3:1(v/w). The medium contained 0.25 M sucrose, 0.1 mM  $MgCl_2$ , 14 mM 2-mercaptoethanol, 25 mM N-morpholino-3-propanesulphonic acid and 3 mM EDTA, pH 8.0. The pH in the final homogenate was about 7.0. The homogenate was squeezed through nylon cloth and recentrifuged at 500g for 10 min after adjusting the pH to 8.0. The supernatant was recentrifuged at 20,000g for 10 min. This supernatant was adjusted to 10 mM  $MgCl_2$ , pH 6.8, irradiated for 5 min with red light and then recentrifuged at 50,000g for 30 min. The pellet was resuspended in the extraction medium and the phytochrome content ( $P_{tot}$ ) was measured in the 50,000g supernatant and 50,000g pellet.

$$\% \text{ Pelletable phytochrome} = \frac{P_{tot} \text{ in } 50,000g \text{ pellet}}{P_{tot} \text{ in } 50,000g \text{ supernatant} + P_{tot} \text{ in } 50,000g \text{ pellet}}$$

$P_{tot}$  was measured at 0 °C with a modified Ratiospect R-2 (ref. 5) using  $CaCO_3$  as scattering agent<sup>6</sup>. All irradiations were carried out at 25 °C. Red light was obtained using a standard red light source<sup>7</sup> (675 W m<sup>-2</sup>). The irradiation with white light was carried out in a phytochamber with xenon arc lamps (7,000 lx).

**Fig. 1** Time course of  $P_{tot}$  (○) and pelletable phytochrome (●) from squash cotyledons in darkness after induction by white light. The first white light exposure began 4 d after sowing.

In the first set of experiments squash seedlings were grown on Vermiculite for 4 d in the dark at 25 °C. After this germination period seedlings received 12 h white light, were returned to the dark for 12 h and then received a further 12 h white light.  $P_{tot}$  and the pelletability were measured in the following dark period every 4 h (Fig. 1).  $P_{tot}$  and pelletability were decreased by the white light treatment. In the dark these variables increased, as expected from earlier observation in which plants were irradiated with red or far-red light<sup>8-11</sup>. In the experimental conditions phytochrome does not seem to be synthesised by a zero-order reaction<sup>8-10,12</sup> but  $P_{tot}$  and pelletability began to oscillate in anti-phase. After about 36 h in the dark they oscillated in phase. The main oscillation period (observed after using the 'moving means' statistical technique) was roughly 24 h.

To investigate the oscillations of phytochrome pelletability in more detail we used the following light regime. Seedlings were grown in the dark for 4 d at 25 °C and exposed to white light for 12 h. To allow sufficient recovery of phytochrome, the first measurement was made after 2 d darkness. In the following dark period phytochrome pelletability was measured every hour for 2 d. The original data of a representative experiment are shown in Fig. 2a; using the three-point moving mean technique

Fig. 2 Time course of pelletable phytochrome from squash cotyledons in darkness after induction by white light (■) or in continuous darkness (●). Seedlings were given only one white light exposure of 12 h.

we obtained the data shown in Fig. 2b. Pelletability oscillated between 20 and 60% and the main period observed was about 12 h. The splitting of the maxima (Fig. 2b) may indicate a second period of about 6 h. The original data indicate the possibility of further oscillations of higher frequencies.

The rhythmic oscillations in  $P_{tot}$  and pelletability were almost certainly attributable to the white light induction period. Without this, pelletability remained constant at about 56%, as shown for the dark control in Fig. 2. Similar rhythmic oscillations could be observed by measuring the pH of the crude homogenate before readjusting it to pH 8.0 (Fig. 3). Again a main period of 12 h and a second period of 6 h could be observed. These oscillations of the pH can be regarded as a marker of the endogenous rhythm of the cell. The oscillation of phytochrome pelletability in nearly the same way as pH oscillations indicates that the rhythm of phytochrome pelletability *in vitro* is not a pure artefact of the experimental method<sup>13</sup>.

These experiments demonstrate a rhythmic change in the ability of pelletable structures to bind phytochrome to 'receptor

Fig. 3 Time course of changes in pH of crude homogenate from squash seedlings in darkness after induction by white light. Data were calculated using the three-point moving mean technique.

sites'. We cannot decide whether the amount of the pelletable structures or their affinity for phytochrome<sup>4</sup> changes rhythmically.

We thank Drs H. Mohr and E. Wagner for discussions, C. J. Beggs for comments on the manuscript and Miss I. Schomerus for assistance. Supported by the Deutsche Forschungsgemeinschaft.

## Hormonal control of insect epidermal cell commitment *in vitro*

DEPENDING on the hormonal milieu, the insect epidermal cell can express one of several differentiated states manifest by the type of cuticle it secretes. In the Lepidoptera, as long as the juvenile hormone (JH) titre is high, the epidermis secretes larval cuticle periodically in response to ecdysone. When the JH titre declines at the end of larval life<sup>1</sup>, ecdysone causes the secretion of pupal cuticle. In the tobacco hornworm, *Manduca sexta*, two distinct releases of ecdysone are necessary for this metamorphosis<sup>2,3</sup>. The first triggers the cessation of feeding and causes the epidermal cells to switch from a commitment to make larval cuticle to one for pupal cuticle<sup>4</sup>. After this time JH can no longer prevent pupal differentiation. The second ecdysone release begins 2 d later and causes pupal cuticle synthesis. Consequently, during the time of the first release it is possible to study the events which occur to alter the cellular commitment unhindered by those events involved

**Fig. 1** *a*, Surface view of typical larval cuticle produced by implanted epidermis from a feeding larva (< 7 g), or from an *in vitro* culture without hormones or with both ecdysone and juvenile hormone. *b*, Cross section of a typical larval cyst. *c*, Surface view of tanned pupal cuticle showing typical pockmarks formed by an epidermal cyst after exposure to ecdysone *in vitro* or *in vivo*. *d*, Cross section of a typical pupal cyst. Scale equals 100  $\mu$ m.

in the expression of this commitment. I report the hormonal manipulation of this cellular commitment in an *in vitro* system.

The dorsal and lateral integument (epidermis and cuticle) from the third to sixth abdominal segments of a 6.2–7.0 g final instar *Manduca* larva was dissected free of fat body and most of the muscle, cut into pieces (approximately 3×5 mm), and explanted to 0.7 ml of Grace's medium (Gibco) in disposable plastic culture wells (Linbro)<sup>5</sup>.  $\beta$ -Ecdysone (Rohto Pharmaceutical) in 10% isopropanol was either premixed with the Grace's medium or added at an appropriate time. C18JH (>95% the natural *trans, trans, cis* isomer; Eco-Control) was dissolved in Grace's medium by sonication<sup>6</sup> in a siliconised (Siliclad) vessel. For the JH experiments the tissue was incubated in the JH-containing media for 3–4 h before  $\beta$ -ecdysone was added. The cultures were incubated in a 95% O<sub>2</sub>–5% CO<sub>2</sub> high humidity atmosphere on a slow rotary shaker (12–16 rotations min<sup>-1</sup>) at room temperature (23–25 °C) for 21–24 h.

The state of commitment of cultured epidermis was then tested by implantation of the pieces into fourth instar larvae before the initiation of the moult to the fifth stage<sup>7</sup>. One or two days after the host had subsequently ecdysed, the implants were recovered. During *in vivo* culture the implanted epidermis grew around its cuticle to form a cyst<sup>8</sup>. During the moult of the host, the epidermis responded to the host's hormonal milieu by forming a new cuticle on the inside of the cyst. The type of cuticle formed reflected the commitment of the epidermal cells at the time of implantation. When epidermis from fourth instar or feeding fifth instar (up to 7 g) larvae was implanted, the cyst formed larval cuticle which was translucent, rubbery and had numerous papillae on its outer surface when viewed at ×400 magnification (Fig. 1*a*). Furthermore, the epidermis was always deeply pigmented (white or blue) as was typical of larval epidermis. Histological sections showed a thick untanned cuticle (Fig. 1*b*) which was identical to cuticle removed from a normal fifth stage larva. In contrast, when epidermis was taken from wandering fifth instar larvae, the cuticle formed was always pupal in spite of the high concentrations of JH in the host<sup>9</sup>. This pupal cuticle was usually hard, shiny, and either tan or white and often had the typical pockmarks of the pupal abdomen (Fig. 1*c*). Figure 1*d* shows this tanning in the cross section of the cyst. Also, epidermis which has formed pupal cuticle no longer contains pigment granules as is typical of pupal epidermis.

Since the cultured epidermis was taken from larvae weighing less than 7 g, 92% ( $n=174$ ) of control pieces

incubated without hormones formed cysts with >90% larval cuticle. When  $\beta$ -ecdysone ( $1 \mu\text{g ml}^{-1}$ ) was added to the epidermis *in vitro*, 92% ( $n=81$ ) of the implants formed pupal cuticle. As the dose of  $\beta$ -ecdysone was decreased, the percentage of cysts forming more than 90% pupal cuticle declined, as shown by the circles in Fig. 2. Many of the cysts from the intermediate doses showed both larval and pupal cuticle; sometimes only tiny spots of pupal cuticle (the size of one to two epidermal cells) were scattered in otherwise normal larval cuticle. Thus, the switchover from larval to pupal commitment seems to be on a cell-by-cell basis as had already been seen in *in vivo* experiments with JH applications<sup>1,10</sup>. Figure 2 shows that the half-maximal dose of  $\beta$ -ecdysone necessary to commit more than 90% of the cells to pupal differentiation is about  $0.1 \mu\text{g ml}^{-1}$  ( $2 \times 10^{-7}$  M). A dose three times smaller ( $8 \times 10^{-8}$  M) is sufficient to alter the commitment in 50% of the cells, as indicated by the triangles in Fig. 2. These amounts of ecdysone are within physiological range; the dose of  $1 \mu\text{g ml}^{-1}$  necessary to effect complete switchover in commitment is the maximum amount detected in the animal at the time of the first release of ecdysone<sup>3</sup>. Also, these data agree well with the concentration of ecdysone necessary to cause evagination in *Drosophila* imaginal disks<sup>11,12</sup>, development of lepidopteran wing disks<sup>13,14</sup>, puffing in *Drosophila* chromosomes<sup>15</sup>, and moulting of *Manduca* proleg crochet epidermis<sup>16</sup>.

The effectiveness of JH in the prevention of this

**Fig. 2** Changeover in commitment of larval epidermis as a function of the dose of  $\beta$ -ecdysone for 18–24 h *in vitro*. ●, Percentage of cysts showing > 90% pupal cuticle. ▲, Percentage of cysts showing > 50% pupal cuticle. (15–30 cysts per point, except nine at  $0.004 \mu\text{g ml}^{-1}$ .)

**Fig. 3** Inhibition of the changeover in commitment of larval epidermis in response to  $\beta$ -ecdysone ( $1 \mu\text{g ml}^{-1}$ ) as a function of the dose of C18JH *in vitro*. ●, Percentage of cysts showing > 90% larval cuticle. ▲, Percentage of cysts showing > 50% larval cuticle. (15–25 cysts per point, except eight at  $0.1 \mu\text{g ml}^{-1}$ .)

ecdysone-induced change in commitment *in vitro* is shown in Fig. 3. The amount of C18JH necessary to prevent pupal commitment of the epidermis in response to a concentration of  $\beta$ -ecdysone of ( $1 \mu\text{g ml}^{-1}$ ) was  $0.1 \mu\text{g ml}^{-1}$  ( $3 \times 10^{-7}$  M). If the cysts showing >50% larval cuticle are considered, then the 50% dose is lowered to  $2 \times 10^{-8}$  M. The concentration of JH in C18JH equivalents in fourth instar *Manduca* haemolymph before the initiation of the larval moult ranges from  $5 \times 10^{-7}$  M to  $2 \times 10^{-8}$  M (ref. 9). Thus, the concentrations of JH necessary *in vitro* are similar to those found in the intact animal. Also, they are two to three orders of magnitude less than those reported to be essential for inhibition of evagination of leg imaginal disks<sup>17</sup> or for inhibition of cuticle deposition in lepidopteran wing disks<sup>18</sup>, even in the presence of the JH-binding protein<sup>19</sup>. In my cultures little or no JH-binding protein was present because of the virtual absence of fat body which produces it<sup>20</sup>. Apparently, in *Manduca* this protein is not essential for the cellular action of JH as suggested by Sanburg *et al.*<sup>19</sup>. Yet it is possible that the discrepancy found between haemolymph concentration and *in vitro* concentrations could be further reduced by addition of the protein.

This simple *in vitro* system now provides an excellent means for study of the cellular events necessary for the metamorphosis of the insect epidermal cell. When exposed to a physiological dose of ecdysone for 22 h, the cells become committed to pupal differentiation unless a physiological concentration of JH is present. Studies are in progress to elucidate the nature of the cellular events which occur in response to ecdysone. Autoradiographic studies of DNA synthesis in the epidermis during late larval life up to the larval-pupal transformation<sup>5</sup> showed no detectable DNA synthesis in this dorsal abdominal epidermis until 2 d after the switchover of commitment *in vivo* (on day 4). Instead massive DNA synthesis occurs in response to the second surge of ecdysone<sup>2,3</sup> the day before cuticle synthesis begins. Thus, the irreversible transformation from larval to pupal determination in the epidermal cells occurs well before DNA synthesis, and presumably reflects some change in regulatory elements in the cell.

I thank Janice Moore and Anna Curtis for technical assistance, and Dr James Truman for critical reading of the manuscript. The work was supported by grants from the US NSF, the Rockefeller Foundation and the National Institutes of Health.

## Suckling mouse cataract agent is a helical wall-free prokaryote (spiroplasma) pathogenic for vertebrates

THE suckling mouse cataract agent (SMCA) is a filterable organism originally isolated from a pooled extract of rabbit ticks (*Haemaphysalis leporis-palustris*) collected near Atlanta, Georgia in April 1961 (ref. 1). The agent grows to high titre in the eyes and brains when inoculated intracerebrally into newborn mice in which it induces cataract, uveitis and chronic brain infection<sup>1–3</sup>. SMCA has also been grown to high titre in embryonated hen's eggs, in which it produces a lethal infection in 4–9 d (ref. 1). The agent has not been grown in tissue culture or in artificial media, but growth in a rabbit lens organ culture has been reported<sup>4</sup>. Stained SMCA-infected tissues failed to show the presence of rickettsiae and, as a result of such negative inferences and other characteristics of the agent<sup>3–5</sup>, it was considered to be a candidate slow virus<sup>6</sup>. Within the past few years however, ultrastructural and biological studies showed that a wall-free prokaryote was consistently associated with the acute and chronic disease in mice and with lethality in chick embryos<sup>7,8</sup>. Although the agent resembled mycoplasmas morphologically, it differed from them in its apparent non-cultivability on conventional mycoplasma medium. We now report that the organism associated with the suckling mouse cataract syndrome is a prokaryote similar to the spiroplasmas—a group of mycoplasmas known previously only from plants and insects.

The general designation 'spiroplasma' was first given<sup>9</sup> to helical, motile, wall-free prokaryotes observed in corn plants infected with the insect-borne corn stunt disease<sup>10</sup>, even before cultivation of the agents in artificial media<sup>11,12</sup>. Similar morphology was also noted for a cultivable mycoplasma recovered from citrus plants infected with "stubborn disease"<sup>13</sup>. Ultrastructural, serological and biological properties of this organism indicated that it deserved recognition as a new genus and species, *Spiroplasma citri*<sup>13,14</sup>. The absence of cell wall material, and other properties, indicated that this organism belonged to the mycoplasmas (Class Mollicutes). Both of the cultured

spiroplasmas induce disease in insects<sup>15,16</sup> and plants<sup>11,12,17</sup>. A third possible spiroplasma has been found in natural populations of four closely related species of *Drosophila*<sup>18</sup>. This agent, termed the sex ratio organism (SRO), is inherited maternally and associated with the absence of males in the progeny of infected females<sup>19</sup>. SRO spiroplasmas have not been cultured and are not known to be associated with plants or higher animals.

A pool of frozen ( $-70^{\circ}\text{C}$ ) allantoic fluid from embryonated eggs taken 5–6 d after SMCA infection with about 100 egg lethal doses (ELD<sub>50</sub>) was passaged in 7-d-old chick embryos. Inoculation (0.1 ml undiluted fluid) was made through the yolk sac into 18 embryos; six uninoculated embryos served as controls. Eggs were incubated at  $37^{\circ}\text{C}$  and candled daily to determine embryo viability.

All embryos receiving SMCA died between 6 and 7 d after inoculation. Uninoculated controls, or embryos inoculated with normal allantoic fluids, were still viable at that time. Allantoic and amniotic fluids were collected, from inoculated and control embryos and examined by darkfield microscopy ( $\times 1,250$ ). Motile, helical microorganisms were observed in allantoic and/or amniotic fluids of all embryos inoculated with SMCA, but were never observed in fluids from control eggs. Numbers of

helical organisms varied from 2 to 5 per microscope field to more than 50–60 per field (Fig. 1a). Continued yolk sac passage of infected allantoic fluids, some containing as few as one helical organism per 10 fields, always yielded fluids containing the motile, helical structures after 3–4 d incubation or when the embryo died. At least 10% of embryonated eggs were used as uninoculated controls in each passage but helical organisms were never seen in fluids of these embryos. The agent was subsequently passaged at least five times each in embryonated eggs from special flocks free of detectable pathogens and mycoplasmas (SPAFAS, Inc., Norwich, Connecticut) or from regular commercial flocks (Truslow Farms, Chestertown, Maryland). No differences in the occurrence or yield of motile, helical organisms were apparent in the two egg sources. Egg passages with selected fresh allantoic fluid, containing numerous helical organisms, reduced the mean day of embryo death from 7.0 to approximately 4.0. Allantoic or amniotic fluids collected 3 d after inoculation, and before most embryos succumbed, were relatively clear and usually contained large number of helices.

We also examined a second, tick-derived, mouse brain-passage isolate (GT-48), which is antigenically indistinguishable from SMCA but causes fatal encephalitis when

**Fig. 1** Appearance of SMCA organisms in chorio-allantoic (CA) fluid of embryonated hen's egg 4 d after inoculation through yolk sac. *a*, Photograph of darkfield preparation of CA fluid showing numerous helical filaments. ( $\times 2,800$ ). *b*, Electron micrograph of negatively stained SMCA. CA fluid was fixed overnight in 1% glutaraldehyde (prepared in 0.15 M NaCl and 0.01 M sodium phosphate buffer, pH 7.2). It was centrifuged at 23,000g and the pellet was resuspended in fresh buffered saline. The droplet was picked up on Formvar-coated grid and stained with 1% phosphotungstic acid (pH 7.2). ( $\times 26,250$ ). *c*, Electron micrograph of thin-sectioned pellet of SMCA spiroplasmas. CA fluid was mixed 1:1 with M1 medium<sup>12</sup> and centrifuged at 23,000g. The pellet was resuspended in fresh M1 medium containing final 1% glutaraldehyde, post-fixed in 1%  $\text{OsO}_4$ , dehydrated in graded series of acetone and embedded in Epon. Sections stained with 2% aqueous uranyl acetate and Reynold's lead citrate. ( $\times 124,000$ .)

inoculated intracerebrally into suckling mice and rats<sup>1,7</sup>. Pooled mouse brain extracts were passaged three times by yolk sac inoculation. Again, helical organisms were observed in all inoculated eggs and in none of the control embryos.

Negatively stained organisms and thin sections of fixed organisms were examined by electron microscopy (Fig. 1b and c). The organisms varied in length from 3 to 8  $\mu\text{m}$  and from 0.1 to 0.2  $\mu\text{m}$  in diameter. One end was usually more pointed than the other and no axial structure was visible. Electron microscopy of thin sections of pellets containing SMCA showed a typical trilaminar unit membrane with no outer wall or envelope and no axial filaments or flagella.

The possible serological relationship of SMCA-associated spiroplasmas to plant and insect spiroplasmas was assessed by precipitin ring or deformation tests, techniques previously used to study serological properties of spiroplasmas<sup>18,20</sup>. Preliminary results (Table 1) suggest that the newly discovered spiroplasmas share some antigenic determinants with *S. citri*, corn stunt spiroplasmas, and SRO. These tests also indicate, however, that they are not serologically identical to other described spiroplasmas—findings reminiscent of earlier data on the relationship of *S. citri*, corn stunt organisms and SRO<sup>18,20</sup>.

The helical organisms from chick embryo-derived SMCA and GT-48 are similar in size to other spiroplasmas (3–12  $\mu\text{m}$  long by 0.1–0.2  $\mu\text{m}$  in diameter)<sup>9–13,18</sup>. They also possess typical rapid rotary or 'screw' motion and flexional movements, neither of which yields to translational motion. Finally, we have seen no evidence of cell wall, axial filaments or other structures characteristic of spirochetes or other true bacteria. Thus, the term "spiroplasma"

seems appropriate for their nomenclature. To these commonly accepted criteria we add a property shared by SMCA-associated organisms and spiroplasmas—the presence of infecting viruses. Negatively stained organisms showed helices with attached round bodies or sacs containing numerous virions characteristic of those designated SV-C3 (spiroplasma virus-citri 3)<sup>21</sup>.

Our findings provide substantial evidence that fluids from infected eggs and mouse brain extracts of SMCA and GT-48 which induce ocular or central nervous system manifestations in mice and rats contain large numbers of spiroplasmas. Ultimate proof of the association of these spiroplasmas with the pathological conditions noted in these hosts, and assessment of the relationship of these organisms to established species of *Spiroplasma*, will depend on cultivation of the organisms in an artificial medium and subsequent information on their biological, serological and pathogenic properties. Published data on SMCA and GT-48 infections, however, suggest a direct relationship. Physical properties reported for the infectious entity<sup>1,7,8</sup> correspond closely to expectations for spiroplasmas. Electron microscopic observations on both egg-cultivated SMCA and GT-48 and the involved eye tissues of mice and rats receiving direct challenge with the same egg materials indicated the presence of mycoplasma-like structures<sup>7</sup>. In retrospect, photomicrographs of the agent in both types of tissue showed numerous curved, wall-free organisms similar in structure to spiroplasmas visualised within plant tissue<sup>10,13</sup>, or to suboptimally-fixed spiroplasmas<sup>13</sup>. We have noted similar structures, again retrospectively, in other micrographs<sup>9</sup> of SMCA-infected allantoic fluids.

Evidence that SMCA spiroplasmas came from the tick rests primarily on the isolation of two lines of helical organisms from different tick pools, reisolation of the agent from these pools<sup>1</sup>, and the absence of similar naturally occurring or latent organisms in pools of other tick species collected at the time<sup>1</sup>, or in numerous normal chick embryo fluids examined. The reported isolation<sup>22</sup> of a similar agent (277F) from the same tick species adds further support to a tick origin. Although the 277F agent was not pathogenic for suckling mice (Swiss line), and was at first considered to be a spirochaete, the reported properties now leave little doubt that it is similar to SMCA and other spiroplasmas.

Identification of a spiroplasma associated with, and presumably inciting, pathological conditions in vertebrates, extends the host range and pathogenicity of these organisms. The ability of organisms within this group to reproduce at temperatures from 30 to 37 °C and their multiplication and persistence in the eye, brain and other tissues of some vertebrate hosts, suggests that a search for these new microbial forms in diseases of unknown aetiology may be very fruitful.

## Plaque-forming factor produced by *Mycoplasma pulmonis*

It has been reported that mycoplasma viruses have been isolated from a number of different mycoplasmas—both *Mycoplasma* and *Acholeplasma* species. All the viruses isolated so far, however, only produce plaques on *Acholeplasma laidlawii* lawns and seem unable to infect the mycoplasma from which they were reputedly derived<sup>1</sup>. Some strains of *Mycoplasma pulmonis* are pathogenic for mice and others are not, and because pathogenicity may be attributable to the possession of a virus, we have searched for viruses that may infect *M. pulmonis*.

Initially, five strains of *M. pulmonis* were grown and examined for plaque-forming activity by the "washing method" used for the isolation of acholeplasma viruses<sup>2,3</sup>. All washes were tested on lawns of colonies prepared from each of the mycoplasma strains. In only one case was a

Fig. 1 Growth curve of *M. pulmonis* JB strain and PFF activity  
●, *M. pulmonis*; ○, PFF.

Fig. 2 Plaques produced by *M. pulmonis* JB strain when overlaid with the Peter C strain. Note the mycoplasma colony in the centre of the single plaques.

zone of inhibition or lysis (plaque) seen and this was where the 'JB' strain washing had been dropped on the lawn of the 'Peter C' strain. The plaque, which extended slightly beyond the area of the drop, was faint but distinct. The titre of the plaque-forming factor (PFF) in the JB wash was found to be  $1 \times 10^5$  PFU ml<sup>-1</sup>.

Subsequently, washings from 34 strains of *M. pulmonis* were placed on lawns prepared from 35 strains. Plaques were observed on 96 of the interactions. These plaques were mostly confluent and comprised a central area of the size of the drop, containing mycoplasma colonies (presumably from the washing fluid), and a distinct zone of inhibition around the periphery about 3 mm wide. There were also a few small isolated plaques the largest being only about 1 mm in diameter.

The relationship between mycoplasma and PFF activity was examined by inoculating GS broth<sup>4</sup> with the JB strain and removing samples at intervals during incubation at 37 °C for mycoplasma counting and assessment of PFF activity. The results (Fig. 1) indicate that the PFF titre corresponds closely with the mycoplasma titre, although about 10- to 100-fold lower. Because of the difficulty of counting the small plaques, we devised a more accurate method of examining the relationship between mycoplasmas and PFF activity. Cultures obtained from all of 90 single colonies grown from filtered (450-nm) cultures showed plaque-forming activity, suggesting that as each colony was probably derived from a single mycoplasma cell, each cell therefore possesses plaque-forming activity.

Larger, more distinct plaques were formed when the JB strain was preincubated before being overlaid with the Peter C strain. The inhibition area round the JB colonies increased in size with the length of preincubation until it reached a diameter of 6 mm after 7 d. Where single plaques were visible, one mycoplasma colony, slightly larger than those constituting the lawn, was observed in the centre of each plaque (Fig. 2).

We then investigated the possibility that the area of agar comprising the plaque contained viable mycoplasma organisms. Colonies of JB strain preincubated for 3 d were overlaid with a culture of Peter C strain. After further incubation, plaques 2–3 mm wide developed round the JB colonies. A duplicate which had not been overlaid with Peter C was used to pick samples of agar 0.5–1 mm from the edge of the JB colonies; these samples and the colonies themselves were tested for viable mycoplasmas. Myco-

plasmas were not isolated from the plaques but they were isolated from the colonies.

The plaques may have resulted from inhibition by acid, produced by the JB colonies, so we compared plaque production on normal GS agar and GS agar maintained at pH 8.5 with HEPES buffer. Plaques were produced equally well on both types of agar. It also seemed unlikely that peroxide production by the JB colonies was responsible for plaque formation as plaques developed in an atmosphere of 95% N<sub>2</sub>-5% CO<sub>2</sub>. The failure of catalase (Boehringer), incorporated in agar medium at a final concentration of 10,000 U ml<sup>-1</sup>, to inhibit plaque development confirmed this.

We tried to transmit the PFF, but washings of plaques produced by JB on Peter C lawns produced plaques that were fainter than the original ones and single plaques picked with a straight wire generally failed to produce further plaques.

The size of the PFF was determined by serial filtration of a JB culture under positive pressure of 5-10 pound inch<sup>-2</sup>, through Millipore membranes of decreasing pore size. The mycoplasma titre of the culture before filtration was  $8 \times 10^8$  colony-forming units (CFU) per ml, and  $5 \times 10^7$  CFU ml<sup>-1</sup> and  $1 \times 10^5$  CFU ml<sup>-1</sup> after filtration through 650-nm and 450-nm membranes, respectively. The titre of the PFF was initially about  $2.5 \times 10^7$  PFU ml<sup>-1</sup> and  $5 \times 10^6$  PFU ml<sup>-1</sup> and  $5 \times 10^3$  PFU ml<sup>-1</sup> after filtration through the respective membranes. Neither mycoplasmas nor plaque-forming activity were detected in the 220-, 100- or 50-nm filtrates.

The filtrates were also examined for their ability to inhibit growth of the Peter C strain in a metabolism inhibition test. No inhibition of growth was detected with the 50-nm, 100-nm and 220-nm mycoplasma-free filtrates. The 450-nm and 650-nm filtrates contained too many mycoplasmas for the test to be useful.

A culture of the JB strain, diluted twofold in phosphate-buffered saline (PBS), was held at 56 °C and viable organisms and PFF activity were determined at intervals. As shown in Fig. 3a, the rate of PFF inactivation was about the same as the rate of organism death. A sample (5 ml) of the same JB culture used for heat inactivation was centrifuged and the deposit resuspended in 0.25 ml of PBS. The suspension was diluted 100-fold in PBS, treated with ultraviolet light, and samples taken at intervals for estimation of mycoplasma viability and PFF activity. The results (Fig. 3b) indicate that when the mycoplasmas died, PFF activity was lost. Treatment with Nonidet P-40 (0.4%) for 15 min at 37 °C inactivated the PFF activity. The titre before treatment was  $1 \times 10^6$  PFU ml<sup>-1</sup> and  $< 2.5 \times 10^3$  PFU ml<sup>-1</sup> after treatment. Samples of a culture of strain JB taken at intervals were incubated at 37 °C for 7 h with Mitomycin C (Sigma) or Kanamycin (Kannasyn, Winthrop), at final concentrations of 1 µg ml<sup>-1</sup> and 5 µg ml<sup>-1</sup>, respectively, after which they were examined for mycoplasma viability and PFF activity. Mitomycin C and Kanamycin abolished both mycoplasma viability and PFF activity. To examine the specificity of the plaque-forming activity of the JB strain, tenfold dilutions of a JB culture were placed on GS agar and preincubated at 37 °C for 4 d. Cultures of *A. laidlawii* (strains M1305/68 and BN1), *A. granularum* (Switzer), *A. modicum* (M45-67-1), *M. bovirhinis* (56R and 190), *M. hominis* (3477/44 and 1100/73), *M. gallisepticum* (S6 and A5969) and *M. arthritis* (PG6 and PG27) were poured over the surface of the different agar plates which were reincubated. Confluent lawns developed with all the mycoplasmas, but plaques only developed around the JB colonies overlaid with the S6 strain of *M. gallisepticum*. Centrifuged deposits of a 48-h broth culture of JB strain were examined under the electron microscope by negative staining, or by touch preparations prepared by methods described pre-

Fig. 3 Inactivation of *M. pulmonis* JB strain and the PFF, by a, heat (56 °C) and b, ultraviolet light treatment. ●, *M. pulmonis*, ○, PFF.

viously<sup>8</sup> Spherical virus-like particles, some about 15 nm in diameter and others about 50 nm in diameter, were frequently observed among the mycoplasma cells. Sections of agar within plaques were also examined but no virus-like particles were seen, so no proof was obtained that the virus-like particles among the mycoplasma cells were associated with plaque-forming activity.

The formation of a plaque on a lawn of the Peter C strain is dependent on the presence of a colony of the JB strain in its centre. In addition, the PFF is inactivated by treatments which also inactivate the JB mycoplasma. The plaque-forming activity also seems to be directly related to the titre of viable mycoplasma organisms as shown by growth and inactivation curves. These observations indicate that the PFF does not develop in the absence of growing JB mycoplasmas. It is intimately associated with the viable JB mycoplasma cell and seems to be inseparable from it. The area of inhibition around a JB colony extends beyond its periphery, however, suggesting that inhibition is due to some diffusible material elaborated by the colony, even though the filtration studies indicate that the apparent size of the PFF is  $> 220$  nm. There is no evidence that such diffusible material is either acid or hydrogen peroxide. The PFF does not have the same characteristics as the mycoplasma inhibitors described by Altucci *et al.*<sup>6</sup> and Furness<sup>7</sup>. Although the PFF seems to have selective activity against certain *M. pulmonis* strains (and *M. gallisepticum*, S6) the inability to propagate plaques serially and to find virus particles within them suggests that plaque formation is not likely to be due to virus production by *M. pulmonis*. The possibility that the PFF is a readily inactivated bacteriocin requires further investigation.

## Enzymatic basis for DDE-induced eggshell thinning in a sensitive bird

ALTHOUGH the thinning of eggshells as a result of ingestion of DDE [2,2-bis-(*p*-chlorophenyl)-1,1-dichloroethylene] is well documented in many sensitive avian species, the underlying mechanism remains unclear (see ref. 1 for review). Risebrough *et al.*<sup>2</sup> have proposed that thinning results from inhibitory action close to the site of shell formation since other physiological processes are apparently not affected in brown pelicans laying eggs with up to 95% thinned shells. Our report of no reduction in blood calcium in white Pekin ducks and ring doves exhibiting DDE-induced eggshell thinning<sup>1</sup> supports the proposal that thinning results from a disruption of shell gland (uterus) function rather than a reduced calcium supply to the gland.

The primary function of the avian shell gland is to secrete calcium and carbonate during eggshell formation. Since large quantities of these substances are not stored in the gland, they must be obtained from the blood (calcium) or from metabolic CO<sub>2</sub> (carbonate) and transported to the calcifying egg<sup>4</sup>. As with other tissues which actively transport calcium, for example the intestine<sup>5</sup>, avian shell gland mucosa possesses both calcium-dependent adenosine triphosphatase (Ca-ATPase)<sup>6–8</sup> and calcium binding protein (CaBP)<sup>9</sup>. Mediators of carbonate (or bicarbonate) transport in this tissue include carbonic anhydrase (CA)<sup>4</sup> and, possibly, anion (HCO<sub>3</sub>)-ATPase<sup>10</sup>; other transported-related enzymes include Na,K-ATPase<sup>6</sup> and Mg-ATPase<sup>6</sup>, a part of which we have found to be oligomycin sensitive. The inhibition of one or more of these transport enzymes by DDE could account for the shell thinning observed in sensitive species. Cooke<sup>1</sup> has suggested that there may be several shell thinning mechanisms and that the relative importance of each is species dependent. We have now found that DDE-induced eggshell thinning in ducks is accompanied by decreases in the activities of two shell gland enzymes, Ca-ATPase and CA, the first apparently more important.

Laying white Pekin ducks (which are relatively sensitive to DDE<sup>11</sup>) approximately 9–12 months old were divided into experimental and control flocks and maintained as in ref. 11. White leghorn hens (which are relatively insensitive to DDE and provide a natural control<sup>2</sup>) approximately 12 months old were assigned to control or experimental treatments and maintained in individual cages. Experimental feed was prepared by adding DDE (40 p.p.m.) to mash before making it into pellets. Eggs were collected daily and shell thickness was measured as in ref. 12. To determine shell gland enzyme activities and DDE residues, birds with a calcifying egg in the shell gland were decapitated and the gland was excised. After rinsing in ice-cold, 0.25 M sucrose the mucosa was scraped and the scrapings were homogenised (10–20% weight per volume) in 0.25 M sucrose. Aliquots were frozen rapidly in a dry ice–acetone bath, freeze dried at –20 °C for 24–48 h and stored at –20 °C until use. The ATPase activity in freeze-dried homogenates was determined using a modification of Bonting's method<sup>13</sup> (Fig. 1 legend gives assay conditions); that of CA in freeze-dried homogenates using the method of Maren<sup>14</sup>, that of CaBP in fresh homogenates using the Chelex procedure of Wasserman and Taylor<sup>15</sup>; DDE residues in dried tissue samples were determined using the method of Cade *et al.*<sup>16</sup>. Protein was determined using the

procedure of Lowry *et al.*<sup>17</sup>. As Bonting<sup>13</sup> has noted, and we have confirmed for shell gland mucosa, freeze drying releases maximal ATPase activity from homogenates, and tissue treated in this manner can be stored at –20 °C for at least three months with no loss of enzyme activity. Pritchard *et al.*<sup>6</sup> have obtained a low Ca-ATPase activity in fresh shell gland homogenates from duck, and Pike and Alvarado<sup>8</sup> have observed a loss of Ca-ATPase activity after storage of fresh shell gland microsomes from quail at 0 or –20 °C for 24 h.

Freeze-dried whole homogenates of duck shell gland mucosa had the following ion-activated ATPases: Ca-ATPase, Mg-ATPase, Na,K-ATPase and anion (HCO<sub>3</sub>)-ATPase. As Fig. 1 shows, the addition of DDE to the ATPase assay medium substantially inhibited all ATPase activities. Their *in vitro* sensitivity to low DDE concentrations varied markedly, however, with only Ca-ATPase and Na,K-ATPase inhibited below 3 p.p.m. The fractionation of homogenates before freezing (method of Homan and Schraer<sup>18</sup>) revealed that the most sensitive Ca-ATPase activity was associated with mitochondria (Fig. 2). These *in vitro* dose–response data are perhaps significant in view of the low gland DDE residues (0.75–1.3 p.p.m.) in ducks

**Fig. 1** Inhibition of ion-activated ATPases in duck shell gland mucosa by DDE added *in vitro* to the assay medium. Each point represents the mean of 3–12 ATPase assays on pooled whole homogenates from 2–4 control ducks. Freeze-dried homogenates were reconstituted in 0.25 M sucrose and 0.2 ml aliquots were added to test tubes containing 0.6 ml buffer and salt solutions. ATPase activity expressed as the rate of inorganic phosphate liberation at 37 °C in *V*<sub>max</sub> conditions after correction for non-enzymatic ATP hydrolysis. Five incubation media were used: A,  $5 \times 10^{-3}$  M CaCl<sub>2</sub>,  $3 \times 10^{-3}$  M ATP,  $92 \times 10^{-3}$  M Tris (pH 7.7); B,  $100 \times 10^{-3}$  M NaCl,  $10 \times 10^{-3}$  M KCl,  $3 \times 10^{-3}$  M MgCl<sub>2</sub>,  $3 \times 10^{-3}$  M ATP,  $92 \times 10^{-3}$  M Tris (pH 7.7); C, medium B, except with  $0.1 \times 10^{-3}$  M ouabain; D,  $3 \times 10^{-3}$  M MgCl<sub>2</sub>,  $2 \times 10^{-3}$  M ouabain,  $69 \times 10^{-3}$  M Tris (pH 7.6); E, medium D, except with  $30 \times 10^{-3}$  M Na<sub>2</sub>SO<sub>3</sub>. Ca-ATPase activity was determined in medium A; Mg-ATPase in medium B; Na,K-ATPase as the difference in activity measured in media B and C; anion-ATPase as the difference in activity measured in media D and E. For the anion-ATPase, sulphite was used as it yielded a proportionately greater activity than bicarbonate. The reaction was started by the addition of 0.2 ml of a solution of  $15 \times 10^{-3}$  M ATP and was terminated 10 min later by the addition of 4 ml of ice-cold colour reagent, a strongly acidic solution of 1% ammonium molybdate in 1.15 N H<sub>2</sub>SO<sub>4</sub> in which 40 mg ml<sup>-1</sup> ferrous sulphate had been dissolved before use<sup>13</sup>. After centrifugation, absorbance was measured at 700 nm. DDE was added to the assay medium in *n,n*-dimethylformamide. The final solvent concentration was 0.5–1%, this concentration did not affect enzyme activity. Control rates of ATP hydrolysis were measured in the presence of solvent alone.  $\Delta$ , Mg-ATPase;  $\circ$ , anion-ATPase;  $\blacktriangle$ , Ca-ATPase;  $\bullet$ , Na,K-ATPase.

Table 1 Effect of DDE feeding on duck shell gland ion-activated ATPases and CaBP

	Control	40 p.p.m. DDE	
	4 d	4 d	1-3 months
Shell thickness (mm)	0.483±0.008 (37)*	0.422±0.014 (5)†	0.395±0.008 (17)†
Ca-ATPase	16.5±0.9 (12)	12.6±1.1 (5)†	11.4±0.9 (7)†
Mg-ATPase	25.5±1.7 (12)	21.4±1.5 (5)	21.7±2.2 (7)
Na,K-ATPase	3.9±0.5 (12)	2.3±0.4 (5)‡	4.4±0.7 (7)
HCO <sub>3</sub> -ATPase	4.6±0.4 (11)		4.8±0.6 (4)
CaBP	5.0±1.1 (5)		4.1±0.7 (4)
Carbonic anhydrase	19.5±1.2 (6)		15.8±0.7 (6)‡

\* Values given as mean ± s.e. (*n*), where *n* is the number of eggs or ducks (enzyme data). Data expressed as mm for shell thickness, μmol Pi released per mg protein per h for ATPases, moles Ca bound per mg protein for CaBP and enzyme units per mg protein for CA. ATPase assay conditions as in Fig. 1, except that HCO<sub>3</sub>-ATPase was determined in media D and E with 25 × 10<sup>-3</sup>M NaHCO<sub>3</sub> replacing sulphite in medium E.

† Significantly different from controls, *P* < 0.01.

‡ Significantly different from controls, *P* < 0.05.

laying thin-shelled eggs (Fig. 3). In contrast, Ca binding to gland CaBP was only inhibited by *in vitro* DDE concentrations above 10 p.p.m.: for example, 30% at 27 p.p.m. Finally, Maren *et al.*<sup>19</sup> have reported that there is no inhibition of duck shell gland CA with *in vitro* DDE concentrations as high as 150 p.p.m.

To determine whether duck shell gland enzymes were affected *in vivo*, we fed 40 p.p.m. DDE to laying birds. In agreement with earlier work<sup>11</sup>, this dietary level caused 13±4% (mean±s.e.) shell thinning after 4 d and 18±3% after 1-3 months (Table 1). Thinning was maximal after about 1 week and then remained constant. The activity of Ca-ATPase in whole gland homogenates from these ducks was reduced 24±10% after 4 d and 31±10% after 1-3 months (Table 1) with no tendency to change during the 1-3 months. The only other significant effects (Table 1) were a transient reduction in Na,K-ATPase activity (41±22% after 4 d), which seems to be unrelated to shell thinning because of the return to normal after 1-3 months, and a limited reduction in CA activity (19±8% after 1-3 months), which exceeds that reported previously<sup>6</sup> (10±4% after 2-3 weeks) for ducks fed 40 p.p.m. DDE.

In contrast to the duck, the activity of Ca-ATPase in chicken shell gland was not inhibited by *in vitro* DDE concentrations up to 15 p.p.m. (Fig. 2). Moreover, 2 weeks of feeding 40 p.p.m. DDE did not affect eggshell thickness, any ATPase, or CA (Table 2), even though gland residues were comparable to those found in ducks laying maximally thinned eggshells (Fig. 3). Finally, to determine whether the Ca-ATPase in duck intestine was also unaffected *in vivo*, we fed 40 p.p.m. DDE to male ducklings for 4 weeks. As Table 3 shows, neither Ca-ATPase nor Na,K-ATPase activities were altered, although DDE residues averaged 1.4±0.3 p.p.m. (wet weight whole intestine).

Table 2 Effect of DDE feeding on chicken eggshell thickness and shell gland ATPase activity\*

	Control	40 p.p.m. DDE
Shell thickness (mm)	0.398±0.007 (12)	0.405±0.006 (12)
Ca-ATPase	12.8±0.8 (11)	11.5±0.6 (12)
Mg-ATPase	21.7±1.9 (6)	23.6±1.8 (6)
Na,K-ATPase	3.1±0.6 (6)	2.4±0.8 (6)
HCO <sub>3</sub> -ATPase	3.8±0.4 (6)	4.8±1.4 (6)
Carbonic anhydrase	25.4±2.1 (6)	24.7±3.7 (6)

\* Experimental birds fed 40 p.p.m. DDE for 2 weeks. Values given as mean±s.e. (*n*), where *n* is the number of eggs or chickens. Units and assay conditions as in Table 1. Shell data are for eggs collected on the last day of the experiment; additional data (not shown) indicated no change in control or experimental shell thickness during the experiment.

Whether CA, a soluble enzyme known to be involved in eggshell formation, can be inhibited directly by water-insoluble organochlorines is a matter of controversy<sup>1</sup>. Certainly, duck shell gland CA is insensitive to DDE *in vitro*<sup>19</sup> and the 10-20% decrease associated with maximal shell thinning *in vivo* (ref. 6 and Table 1) may reflect DDE action at cellular sites controlling enzyme synthesis or degradation. Moreover, since CA in many tissues seems to be present in great excess<sup>20</sup>, 10-20% reduction in the activity of duck shell gland suggests a minor role for CA in shell thinning caused by DDE. This mechanism may be

Fig. 2 Inhibition of Ca-ATPase activity in whole homogenates of duck (solid line) and chicken (dashed line) shell gland mucosa by DDE added *in vitro* to the assay medium. Also included are data for crude mitochondrial (▲) and microsomal (■) fractions of duck homogenate. Each point represents the mean of 4-12 assays on pooled homogenates or fractions from 2-4 control ducks or 4 control chickens; variability, when large enough, is given by s.e. bars. Assay conditions as in Fig. 1. Mitochondrial Ca-ATPase activity was reduced to 30% of control by 15 p.p.m. DDE; control activity in both fractions was 3-4 times higher than in whole duck homogenate. Fractions were prepared by differential centrifugation<sup>18</sup> before freezing, and characterised by the presence of generally accepted marker enzymes: oligomycin-sensitive Mg-ATPase for mitochondria and Na,K-ATPase for microsomes. ATPase activity was negligible in the supernatant fraction.

Fig. 3 Difference in *in vivo* sensitivity to both Ca-ATPase inhibition and eggshell thinning following DDE feeding (40 p.p.m.) in ducks (5–12 birds) and chickens (11–12 birds). Residues are means of values obtained from 4–5 birds. Control duck residues taken from ref. 11. ○, Control; ●, 4 d, ● ≥ 2 weeks. Figures show DDE residues (p.p.m.) in shell gland mucosa

more important in other sensitive species, such as the ring dove, in which Peakall<sup>21</sup> has reported a 60% reduction in gland CA activity during maximal DDE-induced shell thinning.

In contrast, all the available evidence points to a major role for Ca-ATPase inhibition by DDE in the shell gland of the duck. Organochlorines often inhibit membrane-bound enzymes such as the ATPases<sup>22</sup>, and the correspondence between *in vitro* and *in vivo* sensitivities to DDE in ducks and chickens (Figs 2, 3) suggests direct Ca-ATPase inhibition with the duck shell gland enzyme being particularly sensitive for unknown reasons. Moreover, unlike CA, transport enzymes such as Na, K-ATPase and Ca-ATPase do not seem to be present in excess, and partial inhibition is generally accompanied by a parallel reduction in ion transport<sup>13,23,24</sup>. Thus, the close correlation between

## Exposure by phospholipase A of receptors for sheep erythrocytes on human B cells

HUMAN T lymphocytes are known to form rosettes (E rosettes) with certain specific xenogeneic erythrocytes, including sheep erythrocytes (SRBCs). This rosette formation has been widely used as a specific marker for T cells and valuable information has been obtained<sup>1–3</sup>. There is, however, increasing evidence that multiple factors influence the rosette formation; some of these factors can be related to an external effect<sup>4,5</sup> or to the active cell metabolism<sup>6,7</sup>, whereas others are more intimately related to the processes operating during cell maturation<sup>8</sup>. Further, the presence of lymphoid cells carrying E rosette receptors, as well as markers for B cells, has been demonstrated<sup>9</sup>. It has also been demonstrated that neuraminidase treatment induced E rosette formation in a population of lymphocytes bearing B-cell characteristics<sup>10</sup>. Thus, it has not yet been established whether the 'presence of receptor' for E rosette is specific for T cells or not. For this reason, an elucidation of the factors that influence the receptor activity is important if the exact nature of the receptor and the population of cells with it is to be clarified. In the course of investigations on such factors, we have found that treatment of the cells with phospholipase A (PLA) from cobra venom induced the ability to form E rosette in human lymphoblastoid cells that

Table 3 Effect of DDE feeding on duckling intestinal ATPase activity\*

	Control	50 p.p.m. DDE

\* Birds fed 40 p.p.m. DDE for 4 weeks. Values given as mean ± s.e. (n), where n is the number of ducklings. Units and assay conditions as in Table 1.

† Significantly different from controls,  $P < 0.05$ .

Ca-ATPase activity and eggshell thickness in ducks (Fig. 3) is consistent with a cause and effect relationship. Finally, although few details of calcium transport in the avian shell gland are known, the mitochondrial accumulation of calcium seems to be involved<sup>25</sup>, and the *in vitro* sensitivity of the Ca-ATPase associated with this organelle (Fig. 2) suggests that DDE, in fact, inhibits a calcium pump in duck shell gland mitochondria.

We thank David G. Shoemaker, Martha Winsor and Allyn Seymour Jr for technical assistance. This study was supported by the US Public Health Service and the National

are known to be B-cell line. The study also indicated that a population of presumed B cells from the peripheral blood also formed rosettes after such treatment

PLA was purified from lyophilised powder of cobra (*Naja naja*) venom (Sigma) according to the method described by Lankish *et al.*<sup>11</sup> The purified preparation used had an activity unit of 20.8  $\mu\text{mol}$  of released fatty acid per min per mg as assayed using phosphatidylethanolamine (PE) from *Escherichia coli*<sup>12</sup>. The preparations were free from detectable toxic basic proteins and anticomplementary, neuraminidase and protease activities. Human and marmoset lymphoblastoid cell lines were cultivated in RPMI-1640 medium containing 10% foetal calf serum (FCS). Lymphocytes were isolated by Ficoll-Isopaque centrifugation of defibrinated peripheral blood.

**Fig. 1** Rosette formation in Daudi cells treated with PLA. Approximately  $1 \times 10^6$  Daudi cells were incubated at 37 °C in the Tris-HCl buffer, pH 7.2 containing PLA at the indicated concentrations for varying times, washed twice with GVB and then tested for the ability to form rosettes by SRBCs. 0.1 ml of  $1 \times 10^6 \text{ ml}^{-1}$  Daudi cell suspensions were mixed with 0.1 ml of 1.0% SRBCs in the GVB, incubated at room temperature for 5 min and spun at 1,000 r.p.m. for 5 min. After 3 h incubation at 1 °C, the pellet was gently resuspended and the percentages of rosette forming cells (RFCs) were measured (○). Although only the cells with three or more SRBCs were evaluated as RFCs, almost all the RFCs usually had many red cells. All rosette assays were done in duplicate. As a control for 37 °C, Daudi cells treated with 320  $\mu\text{g ml}^{-1}$  of PLA at 4 °C for varying times were tested for the ability to bind SRBCs (●). In this case, even overnight incubation with PLA did not induce rosette formation in the cells.

Daudi cells, as a representative of the human B lymphoblastoid cell lines, were incubated at 37 °C for varying times in the presence of PLA at different concentrations, washed with gelatine Veronal buffer (GVB) and tested for rosette formation by SRBCs. Daudi cells after being treated with PLA, apparently formed rosettes by SRBCs (Fig. 1). The percentages of cells capable of binding SRBCs rapidly increased within 20 min of incubation in the PLA at any concentrations greater than 40  $\mu\text{g ml}^{-1}$  and reached a plateau at 30 min. At that time almost all the cells treated with 320  $\mu\text{g ml}^{-1}$  of PLA could form rosettes. Overnight incubation of Daudi cells in the PLA at 1 °C, however, did not induce any rosette formation. When the SRBCs were incubated at 37 °C for 1 h in the 320  $\mu\text{g ml}^{-1}$  PLA and then tested for their ability to adsorb on the non-treated Daudi cells, no rosette formation was observed. Further, when the mixture of Daudi cells and SRBCs was incubated overnight in the presence of the enzyme at 1 °C and tested for the occurrence of rosettes in the mixtures, no

\* Before PLA treatment, no definite RFC were observed

† These cell lines have been shown to possess the ability to form rosettes<sup>13</sup>. During the passage, however, the cell lines showed decreased ability to form rosettes. At the present time we cannot detect > 0.1% of RFCs in the culture without pretreatment by PLA, although other characteristics of the cells such as lacking of detectable EBV genome remain unchanged.

‡ These monolayer cells were cultivated in Eagle's MEM containing 10% calf serum. Monolayers were split with trypsin, washed twice with GVB and then treated with PLA. No definite RFCs were observed before PLA treatment.

§ Cells were treated with 320  $\mu\text{g ml}^{-1}$  PLA at 37 °C for 30 min and then tested for rosette formation. Values represent means ± s.d. in 2-3 different experiments

rosettes were found. Heating the enzyme at 100 °C for 15 min at pH 8.5 mostly abolished the rosette-inducing activity of the enzyme, whereas heating at 100 °C for 15 min at pH 6.0 did not change the activity. Thus, it can be concluded that the rosette induction may be produced by direct enzymatic action on the Daudi cells, but may not be produced by the effect on erythrocyte membrane or by the agglutinin-like effect bridging across both the cells because of its nonspecific binding to the cell membranes.

The induction of rosette formation by the PLA was observed only in human lymphoblastoid cell lines. Table 1 shows that all of six human lymphoblastoid cell lines including two MOLT cell lines formed rosettes. In contrast, no rosettes could be formed in the other cell lines regardless of the cell species and types. This suggests that the induction of rosette formation with SRBCs by the PLA may be restricted to the lymphoid cells of human species.

The species specificities of indicator erythrocytes capable of adsorbing on the PLA-treated Daudi cells were tested. The lymphocytes from peripheral blood were also tested for rosettes formation by the same series of erythrocytes (Table 2). Sheep, pig and mouse erythrocytes formed rosettes in 53-70% of the lymphocytes which could be included in the T-cell population. This specificity of the

erythrocytes was identical to that of erythrocytes forming rosettes on the PLA-treated Daudi cells.

Several enzymes, including PLA from bee venom and bovine pancreas were also tested for their ability to induce the rosette formation (Table 3). Although bee venom PLA induced rosette formation in a few cells, no other enzymes, including bovine pancreas PLA, could induce a significant rosette formation. It may not be surprising that there was a different effect on the Daudi cells among the three different PLAs. It has been reported that PLAs obtained from these three different sources had different abilities to degrade the phospholipid of human erythrocyte membranes; the erythrocytes were the most sensitive to the *Naja naja* venom PLA, less sensitive to the bee venom PLA and much less sensitive to the bovine pancreas PLA as measured by the degradation of total phospholipid, as well as lecithin, of the cell membranes<sup>14</sup>.

Finally we tested the effect of PLA on E rosette formation in the peripheral blood lymphocytes. The unfractionated and B-enriched lymphocyte preparations were incubated at 37 °C for 30 min in the presence or absence of 320  $\mu\text{g ml}^{-1}$  PLA and, after washing, tested for rosette formation by SRBCs. For the enumeration of B cells the detection of receptors for aggregated IgG was carried out (Table 4). The results show clearly that the values for aggregate binding and rosettes after PLA treatment were apparently above 100%, indicating that a population of B cells, if not all

cells, which possessed the receptor for aggregates acquired the rosette-forming property after PLA treatment.

In conclusion, we have shown that treatment of human lymphoblastoid cells as well as a population of B lymphocytes with *Naja naja* venom PLA resulted in exposure of the receptor(s) for E rosette on the cell. The exposure is probably attributable to the degradation of phospholipids of cell membranes that may cover or competitively inhibit the receptor by a steric hindrance. Earlier studies have demonstrated that the displacement of phospholipids from liver and fat cell membranes by PLA can result in the unmasking of substantial quantities of insulin receptor<sup>16</sup>.

Regardless of the exposure mechanism, our findings and previous studies on the neuraminidase effect on the E rosette formation<sup>10</sup> suggest strongly the possibility that the receptor for E rosette may be present on the human lymphoid cells independently of T or B populations, although, in the latter, it may exist in a state where the activity is masked or inhibited by membrane constituents such as phospholipid and/or sialic acid.

We thank Drs S. Kimura, Y. Akamatsu and M. Nishijima for assay of phospholipase A and Miss Ikuko Suzuki and James Patrie for assistance in the preparation of this manuscript.

## Induction of colony formation *in vitro* by human lymphocytes

THE development of a method for colony formation *in vitro* in semi-solid medium by normal macrophages and granulocytes<sup>1-3</sup>, has been a useful aid in elucidating the control of growth and differentiation of these two types of normal white blood cells and the changes in this control that occur in leukaemia and other diseases<sup>4-6</sup>. The formation of these two types of colonies requires the addition of an inducing protein, which we call MGI<sup>5</sup>, that is found in the appropriate serum or condition medium. This inducer does not induce the formation of lymphocyte colonies and it would obviously be of value to obtain colony formation *in vitro* by normal bone marrow-derived (B) and thymus-derived (T) lymphocytes.

Although induction of macrophage and granulocyte colonies does not seem to require addition of a foreign antigen, normal lymphocytes require antigenic stimulation for differentiation in mass culture in liquid medium<sup>7,8</sup>. This suggested that colony formation with normal lymphocytes might be induced in semi-solid medium by providing the appropriate antigenic stimulus. We have now developed a procedure for colony formation *in vitro* with normal human lymphocytes, by stimulating these cells with the lectins phytohaemagglutinin (PHA) or pokeweed mitogen (PWM). PHA has been reported to be mitogenic for T

lymphocytes and PWM mitogenic for both T and B lymphocytes<sup>9</sup>.

Our experiments were carried out with normal human lymphocytes isolated from peripheral blood after centrifugation on a Ficoll-Hypaque gradient<sup>10</sup>. To obtain the appropriate stimulation,  $8 \times 10^6$  lymphocytes were first incubated with PHA or PWM for 1 d in mass culture in liquid medium in Eagle's medium with 25% autologous human plasma and  $10^7$  erythrocytes. After washing the cells,  $5 \times 10^5$  lymphocytes were generally seeded per 35-mm Petri dish for colony formation in soft agar (0.33%) on a harder agar base (0.5%) (ref. 1) in Eagle's medium and 20% autologous human plasma, with the addition of new PHA or PWM to the lower agar layer.

Fig. 1 Photographs of colonies of human lymphocytes in agar induced by PHA. *a*, Type I colonies 4 d after seeding; *b*, type II colony 6 d after seeding. *a*  $\times 125$ ; *b*  $\times 270$ .

Fig. 2 Number of colonies induced by different concentrations of PHA or PWM. ●, Type I and ○, type II colonies induced by PHA; ■, type I and □, type II colonies induced by PWM. Peripheral blood from healthy adult volunteers was collected with 50 U per ml heparin (pyrogen and preservative free, Evans Medical Ltd). The lymphocytes were isolated by Ficoll-Hypaque gradient centrifugation<sup>10</sup>. Cells from the interphase containing more than 95% lymphocytes were washed 3 times with Eagle's medium with a fourfold concentration of amino acids and vitamins (H-21, Grand Island) and  $8 \times 10^6$  lymphocytes were seeded in  $15 \times 95$  mm plastic tubes with 6 ml Eagle's medium, 2 ml fresh autologous plasma,  $10^7$  autologous erythrocytes and 0.1 ml Bactophytohemagglutinin M (PHA) (Difco) or Pokeweed mitogen (PWM) (Grand Island). After 1 d of incubation at 37 °C in this liquid medium, the cells were washed 3 times with Eagle's medium and  $5 \times 10^5$  lymphocytes were seeded for colony formation in 0.85 ml soft agar (0.33% agar) on a 2.5 ml harder agar base (0.5% agar) per 35-mm Petri dish (No. 1008, Falcon) in Eagle's medium with 20% autologous plasma. Different amounts of PHA or PWM were added to the lower agar layer. Colonies induced by PHA or PWM containing more than 50 cells were counted with an inverted microscope at 5 and 7 d, respectively, after seeding in agar.

Lymphocytes seeded thus gave rise to two types of colonies: the first, which we will call type I, grew inside the upper agar layer (Fig. 1*a*) and the second, type II (Fig. 1*b*) grew on top of the agar. At 5 d after seeding cells in agar with PHA, type I colonies contained up to about 500 cells and type II colonies up to about 200 cells. With PWM, type I and type II colonies contained up to about 200 cells at 7 d. The colonies induced by both lectins had generally degenerated by 10 d and most of the single cells that did not form colonies had degenerated after 3 d. PHA-induced colonies were counted at 5 d and PWM-induced colonies at 7 d. Only colonies containing more than 50 cells were counted. After incubation for 1 d in liquid medium, the cells were agglutinated by both lectins, but these aggregates were dispersed when the cells were washed and there were no such aggregates after seeding in agar. Transfer of both types of colonies to mass culture in liquid medium at 5 and 7 d after seeding with PHA or PWM, respectively, without

adding new lectin, showed that, in liquid medium, the cells from the colonies did not degenerate for at least another 10 d. Cells seeded for colony formation in 1.2% methylcellulose<sup>2</sup> (Dow Chemicals) instead of in soft agar, gave only one type of colony, type I, but the total number of colonies was the same in agar and methylcellulose.

Studies with different concentrations of PHA and PWM have shown (Fig. 2) that the number of colonies formed was related to lectin concentration and that the optimum results were obtained with about 0.03 ml lectin per Petri dish. At this concentration, the total number of colonies with cells from different normal donors was  $491 \pm 98$  for PHA and  $170 \pm 33$  for PWM per  $5 \times 10^5$  cells seeded (Table 1). The number of colonies was related to the number of cells in the range of  $5 \times 10^5$  cells and there were no colonies when the seeding level was below  $10^5$  cells per 35-mm Petri dish (Fig. 3). This suggests that colony formation may require a critical concentration of some factor(s) produced by the seeded cells, in addition to the added lectin.

Mercaptoethanol ( $10^{-4}$ – $10^{-5}$  M), which has been reported to increase the viability of normal lymphocytes<sup>11,12</sup>, did not induce the formation of colonies or enhance the number of colonies induced by PHA or PWM. No colonies were formed when PHA or PWM were omitted either from the preincubation in liquid medium or from the assay for colony formation, indicating that induction of colony formation required the continued presence of the lectin. There were also no colonies, even in the continued presence of the lectin, when autologous human plasma was replaced by foetal calf serum (FCS) in both the preincubation and the colony-forming assay. Substitution of FCS for human plasma only in the assay for colonies, gave at least a 75% decrease in the number of colonies.

Staining of cells from the colonies has shown that both types of colonies induced by PHA or PWM were lymphoblasts, with a similar appearance to the lymphoblasts found after incubation with these lectins in liquid medium. These lymphoblasts did not show phagocytosis of agar. The present procedure did not induce the formation of macrophage, granulocyte<sup>1-3</sup> or erythroid<sup>13</sup> colonies. The formation of lymphoblast colonies by PHA has also been obtained in other experiments with lymphocytes from bone marrow, spleen or peripheral blood<sup>14</sup>.

Cells from the lymphoblast colonies in agar were tested for their ability to form rosettes with sheep erythrocytes (E rosettes) that are formed with human T lymphocytes<sup>15-17</sup> and with sheep erythrocytes coated with antibody (EA

**Table 1** Number of colonies with peripheral blood lymphocytes from five different normal donors

Donor no.	PHA		PWM	
	No. of colonies Type I	Type II	No. of colonies Type I	Type II
1	188	320	55	102
2	131	199	24	90
3	211	423	45	127
4	165	350	66	140
5	155	312	71	129
Mean $\pm$ s.d.	170 $\pm$ 28	321 $\pm$ 72	52 $\pm$ 17	118 $\pm$ 18

The cells were incubated in liquid medium with 0.1 ml lectin and seeded in agar with 0.03 ml lectin. The number of colonies are per  $5 \times 10^5$  cells seeded. In the cultures in liquid medium, there were  $71 \pm 10\%$  blast cells with PHA and  $53 \pm 7\%$  blast cells with PWM, 3 d after seeding.

rosettes) or with antibody and complement (EAC rosettes) that are formed with B lymphocytes<sup>18</sup>. Since cells from isolated colonies were surrounded by considerable amounts of agar even after washing, pooled colonies of both types were incubated overnight in liquid medium, washed and then tested for their ability to form rosettes. Many of the cells from PHA-induced colonies formed aggregates in the rosette assays, but none of the PWM-induced colonies did so. In the assay for E rosettes, there were also some erythrocyte aggregates in the incubations with cells from PHA-induced colonies, but not from PWM-induced colonies. The quantitation of rosette-forming cells was, therefore, more reliable with the cells from PWM-induced colonies. They contained about 60% cells with E and about 25% cells with EA and EAC rosettes. About 10% of the cells were stained for surface immunoglobulin (Ig) by fluorescent anti-human IgG or the Fab fragment of IgG (Miles-Yeda). These results indicate that the PWM-induced colonies formed *in vitro* contained T and B lymphocytes. The PHA-induced colonies contained 60% cells with E rosettes and showed no staining for surface immunoglobulin.

These results, showing *in vitro* colony formation with normal human lymphocytes, should be of value for studies on antigenicity, the immune response and the results of virus infection and lymphocyte diseases. Our finding of optimum colony formation with human plasma should also be of value for studies on the role of plasma factors in the control of growth and differentiation of lymphocytes.

Since these experiments were completed, it has been reported<sup>19</sup> that colonies of lymphoid cells with the B-cell markers, EA rosettes and fluorescent staining for surface Ig but without EAC rosettes, were obtained by adding mercaptoethanol to cultures of mouse haematopoietic organs. We did not obtain colonies by adding mercaptoethanol to isolated normal human peripheral blood lymphocytes, and in our experiments, stimulation with the appropriate lectin produced colonies containing cells with markers for T and B cells.

## Colony formation *in vitro* by leukaemic cells in acute myelogenous leukaemia with phytohaemagglutinin as stimulating factor

HUMAN bone marrow contains cells which form leukocyte colonies of 50 or more cells. Each such colony arises from a single cell<sup>1</sup>, belonging predominantly to the myeloid series<sup>2,3</sup>, which is subject to regulation *in vitro* by humoral colony-stimulating factor generated by peripheral leukocytes<sup>4,5</sup>.

Bone marrow cells in untreated acute myelogenous leukaemia (AML) show abnormal growth *in vitro* in the Robinson assay<sup>6</sup>. Characteristically, there is near total failure of colony formation; predominantly clusters are formed containing 20 cells or less<sup>7,8</sup>. Because such poor proliferation *in vitro* might not represent maximum *in vitro* and *in vivo* proliferation of the leukaemic cells, we have studied several modifications of the *in vitro* culture technique. We report here an *in vitro* system in which marrow cells from untreated AML and AML in relapse were stimulated by phytohaemagglutinin (PHA) to form leukaemic cell colonies in soft agar.

Basically, the PHA assay consists of two phases; an initial liquid phase of 15 h at 37 °C and a semi-solid period of 7 d incubation at 37 °C. In the liquid phase  $2 \times 10^6$  marrow cells per ml of medium (Dulbecco's minimal essential medium + 10% foetal calf serum (FCS) + 10% human serum (HS)) were cultured in Pyrex glass tubes to which 0.05 ml PHA (Difco, PHA-M) per ml medium was added. Bone marrow cells were obtained by aspiration from the iliac crest. The technique used for preparing a marrow cell suspension suitable for tissue culture has been described before<sup>9</sup>. After 15 h of incubation, the cells were washed twice using Hanks' balanced salt solution (305 mosM) and resuspended in agar medium (final concentration agar 0.25%, medium Dulbecco's MEM + 10% FCS + 10% HS). After being resuspended in 0.2 ml agar medium,  $1 \times 10^5$  cells were pipetted into 35-mm Falcon Petri dishes containing 1 ml agar medium (final concentration agar 0.5%, medium Dulbecco's MEM + 10% FCS + 10% HS) to which  $1 \times 10^6$  peripheral blood leukocytes from normal individuals were added using the method of Robinson<sup>10</sup>. Simultaneously,  $1 \times 10^5$  cells were plated in Petri dishes containing agar underlayers without leukocytes. After 7 d of incubation in a 7.5% CO<sub>2</sub> gas-controlled humidified incubator at 37 °C, colonies were visible microscopically. Using an inverted

microscope, the colonies were counted. Aggregates containing 50 cells or more were considered colonies.

Using this PHA assay, we tested the growth of marrow cells from both untreated AML patients and AML patients in relapse. In both cases, the blast cell concentration in the bone marrow exceeded 70%. Moreover, in simultaneous experiments, marrow was tested from leukaemic patients in remission and from haematologically normal individuals. Table 1 summarises the results and shows that *in vitro* colony formation of the marrow from 14 untreated AML patients and from four AML patients in relapse did not occur in the conventional Robinson system. In contrast, colonies were observed in the *in vitro* PHA assay. It seems

**Fig. 1** Ultrathin cross section of a cell in a 7-d-old colony in the PHA assay from marrow of a patient with AML relapse ( $\times 6,750$ ). The nuclear pocket (arrow) and the peroxidase-positive granules are clearly visible. The nuclear pocket is consistent with chromosome abnormalities in the leukaemic cell population<sup>11</sup>.

from the results in Table 1, column 5 that the presence of leukocytes was not essential for colony formation by leukaemic marrow. This contradicts the data of Metcalf *et al.* and Moore *et al.*, who observed no dependence of the presence of leukocytes *in vitro* for leukaemic cell proliferation<sup>11,12</sup>. An explanation for the discrepancy between our results and the Australian data might be that PHA stimulates a different cell sub-population of the leukaemic pool.

**Table 1** Mean number of marrow colonies from AML patients and haematologically normal individuals in the Robinson assay and the PHA assay

Bone marrow	No. of patients	Leukocyte feeder*	Leukocyte feeder	Agar†
Untreated AML	14	0 (0)	99 (14–290)	113 (22–440)
Relapse AML	4	0.5 (0–2)	125 (52–160)	90 (0–130)
Remission AML	10	22 (5–44)	16 (8–46)	0.16 (0–1)
Haematologically normal	5	34 (25–44)	29 (22–35)	0 (0)

\*Mean number of CFU-C per  $10^5$  marrow cells plated. Figures in parentheses represent the range of colonies obtained.

†Cells plated on agar underlayers without leukocyte feeder.

The relationship between the number of cells plated and the number of colonies obtained which was determined in one patient, was linear. This and additional dose-response curves to confirm this observation will be presented later.

Table 1 shows that bone marrow cells in the remission phase of AML form colonies in the Robinson assay as well as in the PHA assay provided that leukocytes are present. The number of colonies scored in the Robinson system is equivalent to that in the PHA assay, indicating no additional effect of PHA on colony formation by marrow cells in remission. Moreover, these data clearly demonstrate the absolute dependence on the leukocyte factor for colony formation by the remission marrow. The same dependence prevails for colony formation of marrow cells from haematologically normal individuals. The similarity of *in vitro* growth between remission marrow and haematologically normal marrow is further evidence for their identity.

Evidence for the leukaemic origin of the bone marrow colonies from untreated AML patients and from AML patients in relapse was obtained by chromosome analysis of cells in the colonies and from morphological studies at the ultrastructural level. These detailed studies will be published soon. Figure 1 shows an electron micrograph of a cell in a colony from the bone marrow of an untreated AML. The nuclear pocket or bleb is apparent on the surface of the nucleus. This morphological alteration is consistently observed in leukaemic cells demonstrating an abnormal chromosome pattern<sup>13</sup>. The karyotype of the leukaemic cell population in this patient was 45,X,-Y,-C,+D,+E,-G, a complex pattern which has been observed in other acute leukaemic patients<sup>14</sup>. Figure 2 shows a colony obtained from the bone marrow of an untreated AML patient. This particular colony consists of approximately 500 cells.

This is a first report of PHA-induced mitogenesis of human leukaemic cells *in vitro*, which is distinct from agglutination of malignant cells by lectins<sup>15,16</sup>. The cultures were checked for cell agglutination immediately after plating. Although in two cases clumps of 2-10 cells were present, in all other cases bone marrow suspensions were distributed in agar as single cells. For this reason further research in technology is needed before an exact assessment can be made of PHA stimulation in every leukaemia.

Fig. 2 Colony cells (7 d old) from an untreated AML in the PHA assay. In this particular colony, 500-700 cells are present ( $\times 45$ ). The leukaemic origin of the colony has been established by electron microscopy.

Aggregation by cellular migration after culture was excluded by counting the number of aggregates in the PHA assay and by comparing that with the number of aggregates in the Robinson system, which was done in eight cases. In all eight cases the total number and size of aggregates in the PHA assay exceeded those in the Robinson assay, which suggests that PHA induced greater cellular proliferation than occurs in the Robinson assay.

Although the mode of action of PHA on the leukaemic cell population is not known, PHA seems to stimulate leukaemic cells to form colonies. But cell types other than leukaemic cells may survive in the PHA *in vitro* cultures. In spite of this, the *in vitro* phenomenon described here demonstrates the growth potential of a leukaemic cell population. It is very important to study whether or not the leukaemic stem cell *in vivo* belongs to the leukaemic subpopulation which is sensitive to PHA *in vitro*. Meanwhile, this *in vitro* phenomenon may be useful in the detection of residual leukaemic cells during the remission phase of AML.

## Development of colonies *in vitro* of mitogen-stimulated mouse T lymphocytes

TECHNIQUES have been developed for the growth of haemopoietic cells (see refs 1 and 2), human T lymphocytes<sup>3</sup> and mouse B lymphocytes<sup>4</sup> on soft agar. Experiments with mouse lymphocytes suggest that concanavalin A (con A) and phytohaemagglutinin (PHA) stimulate T cells<sup>5,6</sup>, whereas pokeweed induces proliferation of both B and T cells<sup>7</sup>. Based on previously described techniques for obtaining clonal growth of human lymphocyte colonies *in vitro*<sup>3</sup>, a procedure has now been developed for inducing clonal proliferation of mitogen-stimulated mouse lymphocytes using a two-layer soft agar technique.

Cells were obtained by removing inguinal and mesenteric lymph nodes and the spleen, in aseptic conditions, from mice of strains ICR, C3H/HeJ, C57BL/6 and congenitally athymic (nu/nu) mice.

The organs were crushed, and passed through stainless steel mesh into cold phosphate-buffered saline. Cell suspensions in Eagle's medium (EM) were cultured at 37 °C in a water-saturated atmosphere with 5-7.5% CO<sub>2</sub> for 48 h in a concentration of 5 × 10<sup>6</sup> per ml EM containing PHA-M (Difco, 0.0125 ml ml<sup>-1</sup>), or con A (Difco, 30 µg ml<sup>-1</sup>), and 5% fresh normal human pooled serum which had been heat inactivated at 56 °C for 30 min. The

mitogen-stimulated lymphocytes were washed twice in EM and the resuspended cells were seeded in the upper agar layer,  $10^6$  cells to each 30-mm Petri dish. The lower agar layer consisted of 2.5 ml medium containing modified Eagle's medium, 20% heat-inactivated human serum, 0.5% agar and  $0.0125 \text{ ml ml}^{-1}$  PHA or  $30 \mu\text{g ml}^{-1}$  con A.

The upper layer (0.85 ml) consisted of EM, 20% inactivated human serum, 0.32% agar, and the seeded lymphoid cells. This was incubated at  $37^\circ\text{C}$  in a humidified atmosphere with 5–7.5%  $\text{CO}_2$ . As controls, cultures were set up in which the lower agar layer did not contain mitogen, or the lymphoid cells present in the upper layer had not been sensitised with PHA or con A.

The development of colonies and their morphology were observed under an inverted microscope at  $\times 50$ . The majority of seeded cells underwent lysis during the first and second days of culture, while the surviving cells proliferated and developed into colonies. Through days 3–5 of culture, each colony was made up of at least 50 cells, with most colonies reaching larger size and containing about 1,000 cells. Following a stationary period of 2–3 d the colonies began to degenerate on day 7 or day 8, and on day 11 the colonies showed complete disintegration with lysis of the cells.

Studies of the cell morphology of the colonies which appeared after 3–4 d, showed all cells to be large and pyroninophilic, resembling in their ultrastructure the blast-like cells which are observed on culturing lymphoid cells in a liquid medium in the presence of PHA or con A. A mitotic index of 5–6% was determined in colony cells after 5 d on soft agar cultures.

When spleen cells were seeded in addition to lymphocyte colonies, macrophage and granulocyte colonies developed, at the same time or 1–2 d later. Also, in some experiments a new kind of colony, composed of large macrophages, developed after days 12–14 and increased in size to day 20.

Similar to the ability of lymphocytes to produce a factor stimulating the growth of bone marrow macrophages and granulocytes<sup>4</sup>, PHA- or con A-sensitised murine lymphocytes in soft agar cultures produced a colony-stimulating factor which may have stimulated the macrophage colonies.

**Fig. 1** Effect of varying the concentrations of PHA in the lower agar layer, and of human pooled heat inactivated serum in the agar layers on development of colonies. ●, 20% human pooled serum; ▲, 10% human pooled serum; ■, 5% human pooled serum.

**Fig. 2** A linear relationship between the number of cells seeded and the number of resulting colonies with either PHA ( $0.0125 \text{ ml ml}^{-1}$ ) or con A ( $30 \mu\text{g ml}^{-1}$ ) in the culture were used. For the same mouse strains, the number of colonies was greatest when PHA was used as mitogen. ●, PHA, ICR; ▲, PHA, C3H/HeJ; ■, con A, ICR.

The number of lymphocyte colonies developing in specific experiments, depended on the mitogen used, the organ of origin, and other specific conditions. We obtained our best results with 20% inactivated freshly pooled human serum, while  $0.0125 \text{ ml}$  PHA or  $30 \mu\text{g}$  con A per  $\text{ml}$  medium gave the best cell preservation, and facilitated the development of large numbers of colonies (Fig. 1). An approximately linear relationship was found between concentration of PHA in the agar layer and number of developing colonies for low concentrations; concentrations exceeding  $0.0125 \text{ ml ml}^{-1}$  depressed colony formation (Fig. 1).

Presensitisation with the mitogens, as well as their continuous presence in the soft agar, were essential conditions for colony formation. Incubation periods with PHA in liquid medium exceeding 48 h did not cause any further significant increase in the number of developing colonies.

A linear relationship was observed between number of cells seeded and number of colonies developing, regardless of whether different mouse strains or different mitogens were used. The potential for colony formation of PHA, in comparison, was higher than that of con A in the same conditions of culture (Fig. 2).

In spite of the fact that a great number of lymphoid cells were seeded ( $10^6$  cells per plate), the ability of clonal proliferation was limited to a minority of transformed lymphocytes. No lymphocyte colonies developed when con A- or PHA-sensitised lymph node or spleen cells of congenitally athymic (*nu/nu*) mice were cultured (Table 1).

**Table 1** The largest number of T-cell colonies were obtained culturing inguinal lymph node cells from different mouse strains using PHA as mitogen

Mouse strain	Mitogen	Lymphocytes prepared from lymph nodes	Number of colonies/ $10^6$ cells (mean $\pm$ s.e.)
ICR	PHA	Inguinal	$120 \pm 7.4$
ICR	PHA	Mesenteric	$80 \pm 8.2$
ICR	Con A	Inguinal	$80 \pm 5$
C3H/HeJ	PHA	Inguinal	$110 \pm 8.2$
C57BL/6	PHA	Inguinal	$170 \pm 16$
C57BL/6	PHA	Mesenteric	$62 \pm 6.4$
congenitally athymic ( <i>nu/nu</i> )	PHA or Con A	Inguinal or Mesenteric	0

No colonies were produced by culturing congenitally athymic (*nu/nu*) mice cells known to be markedly deficient in functional T cells.

To identify the nature of the colony-forming cells, indirect immunofluorescent staining of the  $\theta$  isoantigen<sup>9</sup> was carried out on cells pooled from colonies obtained after 4–5 d of culture of C3H/HeJ lymph node cells. Colonies were removed with capillary tubes, washed three times with Ringer solution containing 5% inactivated human serum, incubated with anti- $\theta$ , washed once more with Ringer solution–human serum; bound anti- $\theta$  was detected by using fluorescein isothiocyanate conjugated rabbit anti-mouse immunoglobulin. The  $\theta$ -bearing cells were revealed by appearance of bright ring-like fluorescence. Demonstration of the  $\theta$  isoantigen in cells of colonies, as well as the failure to obtain cultures from congenitally athymic nude mice, known to be deficient in T cells, indicate that con A- or PHA-stimulated cells capable of developing into colonies in the soft agar system belong to the T-cell series.

This technique for growing and developing mouse T-cell colonies should be valuable for the investigation of lymphoid cells. Its particular advantage is to allow the study of a lymphocyte colony population derived from a particular lymphocyte series possessing the ability to develop into colonies.

## Replacement of serum by hormones permits growth of cells in a defined medium

MOST cell cultures require the addition of serum to synthetic media for their maintenance and growth, and we believe that the primary role of the serum is to provide hormones<sup>1</sup>. We have been led to this hypothesis by a series of experiments showing that serum depleted of certain hormones no longer supports growth of cells, unless the medium is supplemented with the hormones that were removed<sup>2–4</sup>. Clear evidence for the validity of this hypothesis has not yet been obtained because it is difficult to grow cells in the absence of serum. Recently, however, we have succeeded in growing an established rat pituitary cell line, GH<sub>3</sub>, in a defined serum-free medium supplemented with physiological concentrations of four hormones together with the iron transport protein, transferrin. Preliminary investigation shows that serum-free medium supplemented with hormone will also support the growth of several other cell lines.

GH<sub>3</sub> is a functional rat pituitary cell line which produces growth hormone and prolactin<sup>5,6</sup>, and depends on thyroid hormones for growth<sup>1</sup>. Initially, the basal medium used in our growth experiments consisted of 8% charcoal-extracted foetal calf serum. At this concentration of serum, the stimulation by triiodothyronine (T<sub>3</sub>) of the growth of these cells was readily demonstrated. As the serum concentration was decreased in a stepwise manner, we were able to find which additional hormones were required; eventually it was

**Fig. 1** GH<sub>3</sub> cells after 10 d of culture in F-12 medium supplemented with 8% foetal calf serum (8% FCS F-12), serum-free F-12 medium (F-12 SF), and F-12 SF supplemented with hormones. The cells from stock plates (in Dulbecco's modified Eagle's medium supplemented with 12.5% horse serum and 2.5% foetal calf serum) were trypsinised into single cells, treated with trypsin inhibitor, suspended in F-12 SF, and then inoculated at  $1 \times 10^5$  cells per 60-mm plate. The hormones were added at the time of plating. The final concentrations of hormones were  $3 \times 10^{-10}$  M T<sub>3</sub>,  $1 \times 10^{-8}$  M TRH, 50 mU ml<sup>-1</sup> somatomedin preparation, 5  $\mu$ g ml<sup>-1</sup> transferrin and 0.5 ng ml<sup>-1</sup> PTH. At the end of the experiments, both the floating and the attached cells were collected by trypsinisation and centrifugation, treated with Trypan blue, and the live cells counted by haemocytometer. A, 8% FCS F-12; B, F-12 SF; C, F-12 SF + hormones (T<sub>3</sub> + TRH + somatomedin A + transferrin + PTH); D, F-12 SF + hormones minus T<sub>3</sub>; E, F-12 SF + hormones minus TRH; F, F-12 SF + hormones minus somatomedin A; G, F-12 SF + hormones minus transferrin; H, F-12 SF + hormones minus PTH. The first-day cell counts for A and C were identical ( $0.9 \times 10^5$  cells per plate). T<sub>3</sub> and transferrin (human) were obtained from Sigma, TRH is a synthetic peptide and PTH is the synthetic peptide of the first 30 amino acids of human PTH.

found possible to eliminate serum entirely if the medium was supplemented with T<sub>3</sub>, thyrotropin-releasing hormone (TRH), transferrin, the biologically active peptide of parathyroid hormone (PTH), and a partially purified somatomedin preparation (5,000-fold purification from serum)<sup>7</sup>. The effect of these hormones on cell growth is shown in Figs 1 and 2. In the control plates, where neither serum nor hormones were added, there were no live cells after 3 d of incubation. When the five components are present in the serum-free medium, the growth is ~60–100% that in the rich medium (8% foetal calf serum in F-12). If any of the components is not added to the medium, growth either does not occur or is severely depressed. This deficiency is not overcome by substituting other pituitary hormones, steroids, hypothalamic releasing hormones, caeruloplasmin, insulin, glucagon, glycyl-histidyl-lysyl acetate, calcitonin, or prostaglandin E<sub>1</sub>.

The results obtained with GH<sub>3</sub> cells encouraged us to

**Fig. 2** Three cell lines in various media after 7 d in culture. Cells: A, GH<sub>3</sub>; B, BHK; C, HeLa. Media from left to right, 8% FCS F-12, F-12 SF, F-12 SF supplemented with hormones. Hormone additions to GH<sub>3</sub> and BHK are described in the text and in Fig. 3. The final concentrations of hormones added to HeLa cultures were:  $1 \times 10^{-9}$  M TRH,  $10 \text{ ng ml}^{-1}$  SRIF and LRH,  $2 \times 10^{-9}$  M hydrocortisone acetate,  $17 \beta$ -oestradiol and testosterone,  $2 \times 10^{-8}$  M progesterone,  $3 \times 10^{-10}$  M T<sub>3</sub>,  $5 \mu\text{g ml}^{-1}$  caeruloplasmin and transferrin,  $0.2 \mu\text{g ml}^{-1}$  glycyl-histidyl-lysyl acetate,  $50 \text{ mU ml}^{-1}$  somatomedin A,  $50 \text{ ng ml}^{-1}$  insulin and glucagon  $0.5 \text{ ng ml}^{-1}$  PTH and  $0.1 \text{ ng ml}^{-1}$  calcitonin.

study the growth of other established cell culture lines in a defined serum-free medium supplemented with hormones. Initial experiments showed that BHK and HeLa cells do not survive in serum-free medium, but can grow in serum-free medium supplemented with a mixture of 25 hormones. The growth in the latter medium is comparable to that in the rich medium. The growth response of these cells to hormones is shown in Figs 2 and 3. Determinations of the specific hormones which support the growth of these cell lines is in progress.

There have been several reports of the growth of cells in completely defined medium<sup>8-10</sup>. Most if not all of these cases are, however, examples of selection or adaptation of cells to defined culture media. By contrast, our data show that the medium supplemented with hormone substitutes for serum without altering the characteristics of the individual cells or the overall population. Our experiments indicate that a combination of hormones and other specific factors, such as transferrin, can substitute completely for serum. Though the possibility of serial propagation of GH<sub>3</sub> is still under investigation, the results obtained with BHK (Fig. 3) strongly suggest that serum-free medium supplemented with hormones will also support the long term growth of GH<sub>3</sub> cells in a completely defined medium. It has already been shown that hormones can partially substitute for some functions of serum such as the overcoming of density-inhibited growth on changing from serum-containing to serum-free medium<sup>11</sup>.

In these experiments, there is a possibility that residual serum factors are still present and active even after extensive washing. We eliminate this possibility in our experiments in which the cells are transferred from serum-containing medium by trypsinisation into defined medium,

and the growth studied entirely in the defined, serum-free medium. It is important to note that there is no delay in the initiation of growth, suggesting that there is neither selection of cells capable of growth in the serum-free medium, nor extensive adaptation to the growth conditions. Furthermore, growth, in the case of GH<sub>3</sub> cells, is not a nonspecific response to the addition of protein to the serum-free medium. The total amount of protein added (transferrin and the somatomedin preparation) is about  $8 \mu\text{g ml}^{-1}$ . Serum protein equivalent to this protein concentration (0.016% foetal calf serum), when added to the serum-free medium, does not support the growth of these cells, even when supplemented with T<sub>3</sub>. We attribute the growth-promoting activity of the transferrin and somatomedin preparations to these two specific factors, although we recognise that other components within these preparations might also be responsible for stimulation of growth. We are continuing to investigate this as more highly purified preparations become available.

The results presented here strongly suggest that it is possible to eliminate serum from culture medium, and that the main function of serum in cell culture is to furnish hormones. We expect that any cell culture line showing a requirement for serum can be grown in synthetic medium supplemented with a combination of hormones and a few factors such as transferrin. Comparison of the hormonal requirements of GH<sub>3</sub>, BHK and HeLa already indicates that the specific hormones will vary with the cell type, although a few hormones may be common to all cell types. We believe that the elucidation of these requirements will be useful in advancing our understanding of integrated physiology. The possibility of culturing cells in serum-free medium supplemented with hormones will enhance the importance

**Fig. 3** Growth of BHK cells in 10% FCS F-12 and in F-12 SF supplemented with hormones. There were no live cells in F-12 SF only, 4 d after the initiation of culture. The initial plating procedure is as described in Fig. 1. The cells were inoculated at  $1 \times 10^4$  cells per 35-mm plate, and the medium was changed on day 5. The cells, both in the rich medium and in the serum-free medium supplemented with hormones were subcultured on day 8 into the respective media. For subcultures, both trypsin and trypsin inhibitor were also used. On day 8 and on day 13, the cells were washed with buffer, trypsinised, and counted with a Coulter counter. The final concentrations of hormones and factors used were:  $0.5 \mu\text{g ml}^{-1}$  LH,  $10 \text{ mU ml}^{-1}$  FSH,  $5 \mu\text{U ml}^{-1}$  ACTH,  $5 \text{ ng ml}^{-1}$  GH,  $10 \text{ ng ml}^{-1}$  prolactin,  $5 \text{ ng ml}^{-1}$  TSH,  $10 \text{ ng ml}^{-1}$  prostaglandin  $E_1$ ,  $5 \mu\text{g ml}^{-1}$  caeruloplasmin and transferrin,  $0.2 \mu\text{g ml}^{-1}$  glycyl-histidyl-lysyl acetate,  $50 \text{ mU ml}^{-1}$  somatomedin A,  $50 \text{ ng ml}^{-1}$  insulin and glucagon,  $0.5 \text{ ng ml}^{-1}$  PTH,  $0.1 \text{ ng ml}^{-1}$  calcitonin,  $1 \times 10^{-9} \text{ M}$  TRH,  $10 \text{ ng ml}^{-1}$  SRIF (somatotropin releasing inhibitory factor) and LRH (LH releasing hormone). ○, 8% FCS F-12; ●, F-12 SF; ●, F-12 SF supplemented with hormones. LH, FSH, GLH, prolactin (bovine) and TSH were supplied by NIAMD Program of National Institutes of Health; ACTH was obtained from Armour Pharmaceutical Co., Chicago Illinois; caeruloplasmin, transferrin and insulin were from Sigma (Bovine) and glycyl-histidyl-lysyl acetate and glucagon were from Calbiochem. Prostaglandin  $E$  was from Dr J. Pike, Upjohn Co.

of cell culture as an experimental tool, especially in overcoming the present difficulties associated with obtaining primary cultures.

We are grateful for the generous gift of somatomedin preparations from Dr Knut Uthne, Ab Kabi, Stockholm, Sweden, of TRH, SRIF and LRH from Dr Roger Guillemin, Salk Institute, La Jolla, California, and of PTH and calcitonin from Dr Leonard Deftos of the Veterans Administration Hospital, La Jolla, California. We also thank Dr Walter Desmond for comments. This work was inspired by a conversation with the late Gordon Tomkins, and was supported by US Public Health Service grants.

## Interaction of multiplication-stimulating activity with chick embryo fibroblasts demonstrates a growth receptor

MULTIPLICATION-STIMULATING activity (MSA), which is the name given to a family of polypeptides isolated from calf serum<sup>1</sup> and from medium conditioned by certain rat liver cell cultures<sup>2</sup>, stimulates cellular DNA synthesis and growth, and has insulin-like activity. MSA is acid soluble, heat stable and has a molecular weight of approximately 10,000<sup>1,2</sup>. It shares these physical and biological properties with somatomedin<sup>3</sup> and acid-ethanol soluble non-suppressible insulin-like activity (NSILA-s)<sup>4</sup>—polypeptides in human serum which may be important in human growth. We have now studied the interaction of MSA and insulin with chick embryo fibroblasts (CEF). We describe here the binding of labelled MSA to CEF, and correlate this binding with the stimulation of incorporation of <sup>3</sup>H-thymidine into DNA. We propose that MSA and insulin stimulate DNA synthesis in CEF by interacting with a common growth receptor.

MSA was purified from medium conditioned by a cloned line of rat liver cells, BRL-3A<sup>2</sup>, originated by Dr H. Coon. The medium was clarified by centrifugation, chromatographed on Dowex 50 (ref. 2) and twice gel-filtered on Sephadex G-50 in 1 N acetic acid. Fractions which gave a single protein band on disc acrylamide gel electrophoresis at pH 2.7 in 9.0 M urea were used (unpublished results of S.P.N., J. Passamani and P. Short).

Both MSA and insulin<sup>5</sup> stimulated the incorporation of <sup>3</sup>H-thymidine into DNA in tertiary cultures of CEF. The dose-response curves of the two polypeptides were essentially indistinguishable, as were the maximum responses (Fig. 1). Half-maximal stimulation was observed with MSA at  $30 \text{ ng ml}^{-1}$  and insulin at  $45 \text{ ng ml}^{-1}$ . Similar results were reported by Smith and Temin<sup>7</sup>.

When CEF were incubated concurrently with MSA at  $0.5 \mu\text{g ml}^{-1}$ , and insulin at  $0.5 \mu\text{g ml}^{-1}$ —concentrations which separately gave maximum stimulation of <sup>3</sup>H-thymidine incorporation—the stimulation observed was not

**Table 1** Effect of combined addition of MSA and insulin on <sup>3</sup>H-thymidine incorporation in CEF

Addition	<sup>3</sup> H-thymidine incorporation (c.p.m. per dish $\times 10^{-3}$ )
(1) Control	5.7 $\pm$ 0.1
(2) MSA, $0.5 \mu\text{g ml}^{-1}$	21.0 $\pm$ 0.1
(3) MSA, $1.0 \mu\text{g ml}^{-1}$	19.8 $\pm$ 1.4
(4) Insulin, $0.5 \mu\text{g ml}^{-1}$	14.5 $\pm$ 1.2
(5) Insulin, $1.0 \mu\text{g ml}^{-1}$	17.2 $\pm$ 0.3
(6) MSA, $0.5 \mu\text{g ml}^{-1}$ + Insulin, $0.5 \mu\text{g ml}^{-1}$	15.9 $\pm$ 0.2*
(7) 10% Serum	58.9 $\pm$ 2.7

CEF were incubated for 12 h with the additions shown, pulsed for 1 h with <sup>3</sup>H-thymidine, and the radioactivity incorporated into DNA was determined. The mean and range of duplicate determinations are shown. The data obtained with insulin and MSA ( $0.5 \mu\text{g ml}^{-1}$  and  $1.0 \mu\text{g ml}^{-1}$ ) confirmed that  $0.5 \mu\text{g ml}^{-1}$  was a maximally effective concentration.

\*If the effects of MSA and insulin were additive, the incorporation expected would be 29.8.

**Fig. 1** Stimulation of  $^3\text{H}$ -thymidine incorporation in CEF by MSA and insulin. Tertiary cultures of CEF were plated in 0.4% ET (Temin's modified Eagle's medium with 20% by volume tryptose phosphate broth and 0.4% foetal calf serum)<sup>3</sup>. Three days later, insulin (crystalline porcine, Eli Lilly), MSA or ET medium were added at the concentrations indicated. After incubation for 12 h, the cultures were pulsed for 1 h with  $^3\text{H}$ -thymidine, 0.2  $\mu\text{Ci ml}^{-1}$ , and the incorporation of radioactivity into acid-precipitable material (DNA) was determined<sup>6</sup>. The c.p.m. incorporated per 60-mm Petri dish are plotted. The points are the average of duplicate determinations. The incorporation, 2,830 c.p.m., in a control dish which received medium alone, has been subtracted. The MSA and insulin dose-response curves presented are representative. In general, however, the maximal stimulation by MSA (○) is slightly greater than that obtained with insulin (●).

the sum of individual stimulations (Table 1). Since foetal calf serum induced a greater rate of  $^3\text{H}$ -thymidine incorporation, the non-additive effects of insulin and MSA suggested that the two peptides act by a common mechanism. Non-additivity has been observed with insulin and NSILA-s<sup>8</sup>, and insulin and MSA (unpublished results) in human fibroblasts, and with insulin and MSA in 3T3 mouse fibroblasts<sup>9</sup>. In contrast, insulin, MSA and NSILA-s gave

additive responses with serum and fibroblast growth factor in these systems<sup>8,9</sup>.

Polypeptide hormones such as insulin and MSA exert their biological effects by interacting with specific plasma membrane receptors<sup>10</sup>. The apparent common pathway for the stimulation of DNA synthesis in CEF by MSA and insulin could be explained if they utilised the same cell surface receptor. To examine this possibility, MSA was radioactively by the chloramine T procedure as modified by Megyesi *et al.*<sup>11</sup> and the binding of  $^{125}\text{I}$ -MSA to CEF studied.

$^{125}\text{I}$ -MSA bound rapidly and reversibly to CEF at 22 °C. Half the maximal binding was achieved in 45 min, and a plateau of binding was maintained for 3–6 h. Approximately 1–4% of the tracer MSA was bound per  $10^6$  CEF. The bound radioactivity was reduced by more than 70% when incubation was conducted in the presence of an excess of unlabelled MSA ( $1 \mu\text{g ml}^{-1}$ ). Competitive binding with different concentrations of unlabelled MSA gave a steep displacement curve (Fig. 2a). Binding was inhibited 50% by MSA at  $50 \text{ ng ml}^{-1}$  in this experiment, and at  $33 \pm 5 \text{ ng ml}^{-1}$  in 13 experiments. Unrelated peptides failed to inhibit the binding of MSA tracer even in high concentrations: human growth hormone, glucagon and nerve growth factor (A. Liuzzi) at  $10 \mu\text{g ml}^{-1}$ ; epidermal growth factor (R. Ledda) at  $600 \text{ ng ml}^{-1}$ ; and fibroblast growth factor (D. Gospodarowicz) at  $200 \text{ ng ml}^{-1}$ . In contrast, in seven experiments insulin was  $66 \pm 13\%$  as potent as MSA by weight in competing for MSA tracer binding (Fig. 2a).

The near equivalence of MSA and insulin in competing for the binding of MSA to CEF differs strikingly from their relative potencies in other binding systems. In rat liver membranes, for example, MSA is more than four orders of magnitude more effective than insulin in competing for  $^{125}\text{I}$ -MSA binding (Fig. 2b). In cultured human lymphocytes, on the other hand, insulin competes for the binding of MSA tracer appreciably better than does MSA itself (Fig. 2c). This suggests that lymphocytes lack an MSA

**Fig. 2** Binding of  $^{125}\text{I}$ -MSA to CEF rat liver membranes and cultured human lymphocytes. MSA was iodinated with  $\text{Na}^{125}\text{I}$  to a specific activity of  $150 \text{ Ci g}^{-1}$  by a modification of the chloramine T procedure<sup>11</sup>.  $^{125}\text{I}$ -MSA gave a single sharp peak on Sephadex G-50 gel filtration in 1 N acetic acid and co-migrated with unlabelled MSA on disc acrylamide electrophoresis. Tertiary cultures of CEF were detached from the cell monolayer by gentle trypsinisation (0.05% trypsin 0.5 mM EDTA, 37 °C, 5 min). Binding experiments were performed under conditions chosen to give a steady state. *a*,  $^{125}\text{I}$ -MSA, 500  $\text{pg ml}^{-1}$ , was incubated in HEPES binding buffer<sup>12</sup>, pH 8.0, in a total volume of 0.5 ml, with  $2 \times 10^6$  CEF for 3 h at 22 °C; *b*,  $^{125}\text{I}$ -MSA (500  $\text{pg ml}^{-1}$ ) was incubated with purified rat liver plasma membranes (kindly given by D. M. Neville Jr) in 0.15 ml of Krebs-Ringer phosphate buffer, pH 7.4, containing 1% bovine serum albumin for 90 min at 22 °C; *c*,  $^{125}\text{I}$ -MSA (500  $\text{pg ml}^{-1}$ ) was incubated with  $8 \times 10^6$  cultured human lymphocytes (line IM-9) in 0.5 ml of HEPES binding buffer, pH 8.0, for 90 min at 15 °C. The indicated concentrations of unlabelled MSA (●) and insulin (○) were added together with tracer MSA and were present throughout the incubation. In each experiment, cells or membranes are pelleted by centrifugation for 1 min in a Beckman Microfuge, the pellets were excised and the bound radioactivity was determined. The total binding was 48%, 3.7% and 6.2% of the tracer radioactivity in the three experiments, respectively. Maximum binding has been plotted at 100%.

receptor, tracer MSA binding exclusively to lymphocyte insulin receptors. The poor competition by unlabelled MSA is consistent with its low insulin-like activity (<1% the potency of insulin). Analogous results have been reported for NSILA-s binding to rat liver membranes and cultured lymphocytes<sup>11</sup>.

CEF have insulin receptors (our unpublished results) similar to those in other tissues<sup>13,14</sup>. The MSA binding we have observed, however, clearly is not binding to an insulin receptor. <sup>125</sup>I-insulin binding to insulin receptors is inhibited by different peptides in proportion to their insulin-like biological activities. MSA and NSILA-s, which have low insulin-like activity, compete poorly for the binding of insulin tracer. In contrast, they are more than 250 times more potent competitors for MSA binding than for insulin binding in CEF (our unpublished results). Porcine proinsulin is 20 times more potent in competing for MSA binding than for insulin binding (our unpublished results). Scatchard plots of insulin binding data are characteristically curved<sup>15</sup>. This results from negatively cooperative site-site interactions among insulin receptors<sup>15</sup>. In contrast, Scatchard plots of MSA-binding data are linear (our unpublished results). We have been unable to demonstrate cooperative interactions among MSA receptors.

In summary, CEF possess MSA receptors with a unique specificity, that is, insulin competes almost as well for tracer MSA binding as MSA itself. The CEF MSA receptors differ from insulin receptors, MSA receptors of rat liver membranes, and NSILA-s receptors in CEF<sup>16</sup>. MSA and insulin stimulate DNA synthesis in CEF with nearly identical dose-response curves. Their effects are not additive. The same MSA concentration induces half-maximal <sup>3</sup>H-thymidine incorporation and inhibits tracer MSA binding by 50%. MSA preparations at different stages of purification and inactivated MSA compete for tracer MSA binding in proportion to their potencies in stimulating <sup>3</sup>H-thymidine incorporation (our manuscript in preparation). Taken together, these properties suggest that the MSA receptor we have demonstrated in CEF is a physiologically relevant growth receptor, mediating the growth-promoting effects of MSA and insulin.

## Two sex steroid receptors in mouse fibroblasts in culture

WE report that the mouse fibroblasts known as L-929 cells have androgen and oestrogen receptors (R-A and R-E), as well as the glucocorticosteroid receptors (R-G) reported earlier<sup>1,2</sup>. This observation may lead to an increased interest in L cells as they provide a convenient system for studies of the biology and pharmacology of hormones at the cellular level.

L-929 cells provided by J. Zeuthen, Institute for Human Genetics, Aarhus, who obtained them from the American Type Culture Collection, and found that they had 56-76 chromosomes, with a modal number of 66 (personal communication). Cells were grown in plastic Petri dishes, or in suspension using Dulbecco's modified Eagle's medium supplemented with 10% heat inactivated calf serum, bovine insulin (0.12 U ml<sup>-1</sup>) and antibiotics. At confluence, cells were collected by scraping the dishes with a rubber policeman, or by low speed centrifugation from suspension. After washing in cold phosphate-buffered saline, cells were homogenised in a small volume of TET-buffer (Tris 15 mM,

Fig. 1 Ultracentrifugation of L-929 cell cytosol preincubated with radioactive dexamethasone, androstanolone and oestradiol on linear 5-35% glycerol density gradients in TET buffer. Cytosols were labelled at 0-2 °C for 3 h and 0.3 ml samples were centrifuged at 149,000g<sub>av</sub> for 18 h at 0-2 °C. Thirty-four fractions (2 drops) were collected (abscissa), counted and the results expressed in fmol of radioactive steroid (ordinate). ○—○, 1 nM <sup>3</sup>H-dexamethasone; ○—○, 1 nM <sup>3</sup>H-dexamethasone plus 100 nM unlabelled dexamethasone; ×—×, 1 nM <sup>3</sup>H-androstanolone; ×—×, 1 nM <sup>3</sup>H-androstanolone plus 100 nM unlabelled androstanolone; ●—●, 1 nM <sup>3</sup>H-oestradiol; □—□, 1 nM <sup>3</sup>H-oestradiol plus 100 nM unlabelled oestradiol.

**Fig. 2** Scatchard plot of binding data for androstanolone and oestradiol by L-929 cell cytosol. Binding of  $^3\text{H}$ -androstanolone ( $\bullet$ ) and  $^3\text{H}$ -oestradiol ( $\square$ ) in the 105,000g cytosol (4.9 mg protein per ml) from L cells, using increasing concentrations of steroid from 0.2 nM to 100 nM. Specific binding was determined after exposure to charcoal-dextran (5.0–0.5 mg ml $^{-1}$  TET buffer) at 0 °C for 30 min followed by centrifugation and counting of the supernatant.

EDTA 1 mM, dithiothreitol 1 mM, pH 7.4) in a glass-glass homogeniser. The cytosol fraction was obtained after alternate centrifugations at 700g for 15 min and 105,000g for 60 min. Looking for the cytosol receptor, we used purified  $^3\text{H}$ -steroids: androstanolone (5 $\alpha$ -androstane-17 $\beta$ -ol-3-one; 175 Ci mmol $^{-1}$ ), dexamethasone (9 $\alpha$ -fluoro-16 $\alpha$ -methyl-11 $\beta$ , 17,21-trihydroxypregn-1,4-diene-3,20-dione; 27 Ci mmol $^{-1}$ ), 17 $\beta$ -oestradiol (60 Ci mmol $^{-1}$ ), progesterone (48 Ci mmol $^{-1}$ ) and R5020 (17,21-dimethyl-19-nor-4,9-pregnandiene-3, 20-dione; 51.4 Ci mmol $^{-1}$ ). Binding was achieved after incubation at 0–2 °C for at least 2 h, mostly at 1 nM. Unlabelled compounds were used in isotopic dilution experiments to assess nonspecific binding by a subtraction method or to measure binding inhibition, and to calculate

the number of binding sites and the  $k_{\text{deg}}$  for a series of measurements made with different concentrations of steroids. Binding was evaluated either by using a charcoal suspension to remove free and rapidly released steroids, or by ultracentrifugation through linear 5–35% glycerol Tris gradients as described before<sup>4–6</sup>.

A symmetrical radioactive 7–8S peak was obtained after labelling with 1 nM  $^3\text{H}$ -androstanolone,  $^3\text{H}$ -oestradiol or  $^3\text{H}$ -dexamethasone. No binding was observed after incubation with progesterone or R5020, a progestational agent of high affinity for progesterone receptor in the uterus and mammary gland. As Fig. 1 shows, the radioactive 7–8S peak of R-G was greatest, while that of R-A was twice as high as the R-E peak. Addition of the corresponding unlabelled steroid (100 nM) to the 1 nM  $^3\text{H}$ -tracer almost abolished the radioactive 7–8S peaks of R-A and R-E, while 15% of R-G binding remained in the 7–8S area. In the 4S region of the gradient, no binding was observed with  $^3\text{H}$ -androstanolone but some nonspecific binding (not depressible by isotopic dilution) was seen with  $^3\text{H}$ -oestradiol and  $^3\text{H}$ -dexamethasone. Treatment with Pronase (1 mg ml $^{-1}$ ) for 2 h at 0 °C abolished the 7–8S peak of 1 nM  $^3\text{H}$ -androstanolone and  $^3\text{H}$ -oestradiol in the cytosol.

After incubation with various concentrations of steroid (0.25–100 nM), the Scatchard plot of the data (Fig. 2) indicated  $k_D \sim 0.25$  nM for androstanolone and 0.20 nM for oestradiol with 47.8 and 23.5 fmol mg $^{-1}$  protein of cytosol (measured by the Lowry method), respectively, corresponding to about 3,000 and 1,500 sites per cell (calculated from the cell number).

Specificity studies by competition assays with unlabelled steroids (100 nM, Table 1) suggested that the three binding sites are probably associated with three distinct and non-interacting sites, and that they are similar to the oestrogen, androgen and glucocorticosteroid receptors described in many mammalian target organs<sup>4–6</sup>. Oestrogens such as the non-steroid diethylstilboestrol (DES) compete with  $^3\text{H}$ -oestradiol for receptors, but cortisol, progesterone and androgens do not interfere significantly with the binding of oestradiol.  $^3\text{H}$ -androstanolone binding is inhibited by androstanolone and testosterone, and to a smaller extent by progesterone and cyproterone acetate, an anti-androgen (of the progesterone series), and by oestradiol, but neither DES nor cortisol competes significantly. These results cannot be explained by the presence of a single binding site, but they are compatible with two sites, R-A and R-E. The same strict oestrogen specificity for R-E has been observed in all oestrogen sensitive tissues studied so far, while competition by androgens, progesterone, anti-androgens and oestradiol, but not DES, has also been observed with all androgen receptors<sup>3,7–10</sup>.

Furthermore, the small degree of competition between  $^3\text{H}$ -dexamethasone and androstanolone or oestradiol, and conversely the virtual absence of competition on R-A and

**Table 1** Specificity studies for steroid receptors in L-929 cells

Dexamethasone	—	—	22

Samples of cytosol were incubated at 0–2 °C with  $^3\text{H}$ -steroids with or without unlabelled steroids for 3 h, and bound radioactivity was obtained after 30 min of exposure to charcoal-dextran (as described in Fig. 2).

\*100 expresses the binding with 1 nM  $^3\text{H}$ -steroid and corresponds to 18.0 fmol bound androstanolone, 9.4 fmol bound oestradiol and 40.0 fmol bound dexamethasone per mg cytosol protein, respectively, for R-A, R-E and R-G.

R-E binding by cortisol favour independent R-G binding sites. No progesterone receptor was detected.

To investigate nuclear receptors, we obtained nuclei from the pellet of the homogenate after centrifugation at 700g for 15 min. Nuclei were suspended in 0.25 M sucrose, 1 mM MgCl<sub>2</sub> and 10 mM Tris buffer, pH 7.5, containing 1% Triton and washed three times in the same buffer without Triton. We looked for the nuclear receptor by incubating the nuclear suspension directly, or after labelling the 0.5 M KCl nuclear extract. In the first case, nuclei were resuspended in sucrose buffer and samples were incubated with 1 nM or 5 nM tritiated steroids, alone or with a 100-fold excess of the corresponding unlabelled compound for 1 h at 0 °C followed by 2 h at 20 °C. After washing three times with excess buffer followed by methanol extraction of the pellet, no specific binding was observed. By the other approach, the washed nuclear pellet was extracted with high salt buffer (TET-0.5 M KCl), centrifuged at 105,000g for 60 min and the soluble extract was incubated with 1 nM or 5 nM tritiated hormones and tested for binding by charcoal-dextran or density gradient centrifugations. No specific binding could be observed as in target tissue nuclei from hormone-deprived animals<sup>4-6</sup>. This was compatible with the presence of a very small or insignificant amount of steroid in the medium (verified by direct radio-immunoassays), and facilitated further study of hormonal effects on receptor distribution.

Cells were incubated for 30 or 60 min with 5 nM <sup>3</sup>H-androstanolone or <sup>3</sup>H-oestradiol at 37 °C in 5% CO<sub>2</sub> in air. A 5.3S peak was obtained in the 0.5 M KCl extract after gradient ultracentrifugation analysis, corresponding in the case of <sup>3</sup>H-androstanolone to 20.6 fmol mg<sup>-1</sup> protein after 30 min, and 23.7 fmol mg<sup>-1</sup> after 60 min of incubation. In the cytosols, analysed on glycerol-Tris gradients, 4.6 fmol mg<sup>-1</sup> protein remained in the 7-8S peak after 30 min and 3.6 fmol mg<sup>-1</sup> after 60 min. After 60 min of incubation with <sup>3</sup>H-oestradiol, the 5.3S nuclear peak corresponded to a protein concentration of 9.4 fmol mg<sup>-1</sup> and the 7-8S cytosol peak to 1.2 fmol mg<sup>-1</sup>. As in other systems<sup>11</sup>, about 40% of nuclear radioactivity was not extracted by KCl buffer, and was not studied further. When the cells were incubated together in 5 nM <sup>3</sup>H tracer and 500 nM unlabelled steroid, no 5.3S peak was observed in the nuclear extract.

These results suggested that, as in all steroid-sensitive cells the cytosol receptors in L-929 cells are transferred into the nuclei in the form of <sup>3</sup>H-steroid-receptor complexes after brief exposure of L cells to the appropriate hormone at 37 °C.

As the three cytosol receptors had the same S value on gradient ultracentrifugation, we investigated whether two or three of the different binding sites could belong to the same macromolecule. We reasoned that, if this is the case, the transfer of the oestradiol receptor into the nucleus would leave available androgen binding sites in the soluble nuclear extract (and vice versa for the transfer of R-A). But no binding was observed, after exposure of cells to 5 nM unlabelled oestradiol at 37 °C and secondary labelling of the nuclear 0.5 M KCl extract for 2 h at 0 °C with 1 nM <sup>3</sup>H-androstanolone. Similar results were obtained with incubation in other steroids followed by hetero-labelling and all results were negative.

Therefore, we conclude that R-A, R-E and R-G are distinct binding molecules, as already observed for R-A and R-E in MI<sub>1</sub> cells<sup>3</sup> and in the uterus and prostate<sup>12,13</sup>. These data for cell lines such as MI<sub>1</sub> or L suggest that different receptors are present simultaneously in a single cell, an impossible conclusion for organs made up of various cell types. In the case of the uterus, however, the induction of oestradiol and progesterone receptors by progesterone and oestradiol, respectively<sup>14-16</sup>, favours the likelihood of a cellular multiplicity of types of receptor within a cell.

Thus by all criteria of binding affinity and specificity, physicochemical properties, cell distribution and nuclear transfer L-929 cells contain three typical steroid receptors, very similar to functional target organ receptors detected already. This supports the concept of cellular plurality of receptors, which in turn should be studied in terms of potentially different interactions with the genome<sup>6,17,18</sup>. It is interesting that oestradiol, the native oestrogen, can, in a given cell, interact with two specific proteins, R-E and R-A, of different affinities, and that a synthetic oestrogen, DES of great therapeutic interest<sup>19</sup>, binds strongly to one of them, R-E, and very little to the other, R-A.

Are these receptors vestigial and unable to mediate steroid effects? Our preliminary observations of L-929 cells growing in the presence of steroids show that with 30 nM androstanolone, there is a moderate increase of growth rate. Moreover, after 10 d of suspension culture with this androgen, the amount of cytosol R-E per mg of cytosol protein decreases approximately 50% (which is not explained by an increase of nuclear binding sites). Conversely, after 10 d in 30 nM DES (17 $\beta$ -oestradiol cannot be used because it binds to R-A), there is no decrease in R-A sites in the cytosol. Macromolecular syntheses (total proteins and DNA) are also changed by different steroid concentrations and combinations. Normal fibroblasts (ref. 20 and A. Groyer and P. Robel, unpublished) contain sex steroid receptor(s), and it will be interesting to see if these cells are more endocrinologically competent than previously believed.

We thank C. Corpéchet for purified <sup>3</sup>H-steroids. Unlabelled steroids and <sup>3</sup>H-R5020 were provided by Roussel-Uclaf (Dr J. P. Raynaud). Partial support came from Délégation Générale à la Recherche Scientifique et Technique and the Ford Foundation.

## Hereditary persistence of foetal haemoglobin with $\beta$ -chain synthesis in cis position ( $\gamma$ - $\beta$ <sup>+</sup>-HPFH) in a negro family

HEREDITARY persistence of foetal haemoglobin (HPFH) is an uncommon condition described mainly in negroes and Greeks. Although this genetic disorder is rare, it has been very important in the study of the arrangement of human globin genes on chromosomes and in the investigation of the regulation of foetal haemoglobin synthesis. It is not

always possible to distinguish clearly between HPFH and thalassaemia and there is considerable genetic heterogeneity in these conditions. A majority of patients with HPFH have an increased amount of foetal haemoglobin, normal or near normal red cell indices, Hb F in each red cell, an absence of clinical manifestations in the simple heterozygous state or in combination with Hb S, Hb C, or Hb E, and balanced globin synthesis<sup>1</sup>. Two different forms of  $\gamma$  chains are normally synthesised, with either glycine or alanine at the  $\gamma^{136}$  position. Although the majority of negro heterozygotes for HPFH have both glycine and alanine at  $\gamma^{136}$ , several patients have had only glycine<sup>2-5</sup>. There was no synthesis of  $\beta$  or  $\delta$  chains in the *cis* position to the HPFH gene in any of the appropriate negro cases reported previously. We describe here a negro family in which the proposita had Hb S-HPFH with  $\beta$ -chain synthesis in the *cis* position to the HPFH gene.

In a screening study conducted in high schools in Philadelphia, an asymptomatic female teacher with unusual proportions of Hb S, Hb A, and Hb F was detected by cellulose acetate electrophoresis. The Hb S level was 40.9%, Hb F 29.7%, Hb A 27.5% and Hb A<sub>2</sub> 1.9%. The presence of Hb S was confirmed by the dithionite-phosphate solubility test<sup>6</sup> and by precipitation during shaking of the oxy-form of the haemoglobin<sup>7</sup>. On acid elution of peripheral blood smears<sup>8</sup> all her red cells were found to contain Hb F, but in varying amounts. Further study of the patient revealed that she had never experienced symptoms of sickling, but that her red cell morphology as well as her red cell indices and reticulocyte count were normal. A study of her family (Table 1) showed that her husband, her putative father and her sister were normal, but that her 9-month-old son had an Hb F level of 22.1% and an Hb A<sub>2</sub> of 1.1% with normal red cell indices and Hb F present in every red cell. Her mother had sickle cell trait with Hb S of 40.0%. A study of 12 different blood group systems in the proposita and her parents failed to exclude paternity. Globin synthesis studies were performed on each member of the family (Table 1). The results showed balanced globin synthesis in each individual, a result in agreement with the normal red cell indices in failing to detect evidence of thalassaemia in this family. In the proposita the  $\beta^A/\alpha$  and  $\beta^S/\alpha$  specific activity ratios were near unity (1.06, 1.08), results different from the decrease in one or both of these ratios found in negroes with Hb S- $\beta^+$  thalassaemia<sup>10</sup>. Analysis of the glycine and alanine residues in the third portion of the  $\gamma$  chain after cyanogen bromide cleavage<sup>11</sup> gave values in the proposita of glycine 1.02 and alanine 1.97, and in her son of glycine 1.07 and alanine 2.01. These findings may be interpreted as consistent with production of chains with only glycine at  $\gamma^{136}$ .

The presence of HPFH in the proposita and her son is indicated by Hb F being present in all red cells, normal haematological values, balanced globin synthesis and the lack of interaction with Hb S. This family is of special interest in that  $\beta$ -chain production is present and directed

by the chromosomes which contains the HPFH determinant, in contrast to all other negro varieties previously described. The HPFH gene in the negro family described here differs from the British<sup>12</sup> and Greek<sup>13</sup> types in the higher amount of Hb F produced and in the content of only glycine at  $\gamma^{136}$ . Production of  $\beta^A$  chain by the affected chromosome probably occurs in all three varieties. Although the child of the proposita clearly has HPFH, neither parent of the proposita has this condition. Non-paternity was not demonstrated by the studies performed, but either this or a mutation are possibilities in this family.

The majority of patients with HPFH have balanced globin synthesis, although three negro heterozygotes and one homozygote have had clearly decreased ratios<sup>1,12,14,15</sup>. Although many negro heterozygotes with  $\beta$  thalassaemia have normal globin synthesis ratios<sup>16,17</sup>, the findings in this family are not consistent with the presence of  $\beta$  thalassaemia; nor are the normal globin synthesis studies and haematological values<sup>18</sup>.

Studies involving patients with haemoglobin Kenya have indicated that the genes for  $\gamma$ ,  $\delta$  and  $\beta$  chains are closely linked on the same chromosome<sup>19,20</sup>. In the previously described forms of negro HPFH the findings may be attributed to the deletion of the  $\delta$  and  $\beta$  chain loci, together with some controlling regions which allow continuing synthesis of  $^G\gamma$  and  $^A\gamma$ , or only  $^G\gamma$ . In the present family, the low Hb A<sub>2</sub> values suggest that the  $\delta$ -chain locus may be deleted. The total deletion in this family may therefore involve the  $^A\gamma$  and  $\delta$  loci and some controlling regions, leaving  $^G\gamma$  and  $\beta$  chain synthesis intact. It is of interest that in the proposita the percentage of Hb S is almost identical to that found in her mother and similar to that usually found in sickle cell trait, demonstrating that the combined synthesis of Hb F and Hb A directed by the HPFH chromosome is similar to the synthesis of Hb A seen in sickle cell trait and greater than the synthesis of Hb S. As observed in this patient and in other negro heterozygotes for Hb A-HPFH or Hb S-HPFH, the limit of Hb F synthesis per cell seems to be approximately 30–35%. In patients with Hb S- $\beta^0$ -HPFH, the normal haemoglobin content of the cell is achieved by compensation from the  $\beta^S$  gene, which is responsible for approximately 70% of the total haemoglobin production. In Hb S- $\beta^+$ -HPFH described here, Hb F still comprises only 30% of the total haemoglobin in the cell, although Hb A is now responsible for the compensatory synthesis which results in a normal mean cell haemoglobin value. Another family with similar characteristics has recently been found<sup>21</sup>.

The presence of Hb A in the proposita indicates that genetically directed Hb synthesis may persist in each red cell without loss of the  $\beta$  chain cell locus. The importance of this finding is that a variety of defects seem to control HPFH, suggesting that a search for the biochemical defects in these various conditions may provide clues for influencing the synthesis of Hb F in persons who retain  $\beta$  chain

Table 1 Haematological and globin synthesis data on family members

Subject	Age	Hb (g dl <sup>-1</sup> )	MCV ( $\mu$ m <sup>3</sup> )	MCH (pg)	Phenotype (Hb)	Hb A <sub>2</sub> (%)	Hb F (%)	non- $\alpha/\alpha$
Proposita	27	12.0	92.0	30.6	SFA	1.9	29.7	1.08
Husband	28	15.2	92.0	31.5	A	2.9	0.1	0.92
Son	9/12	11.7	82.0	27.7	AF	1.1	22.1	1.17
Sister	23	12.3	90.0	29.4	A	2.4	0.4	1.06
Mother	56	13.1	88.0	29.7	AS	—	0.3	1.03
Father	67	14.4	88.0	29.7	A	2.9	0.8	0.97

The non- $\alpha/\alpha$  ratio was determined after incubation of peripheral blood with <sup>14</sup>C-leucine for 2 h at 37 °C, preparation of haemolysate and separation of the globin chains by chromatography on carboxymethyl cellulose in 8 M urea at pH 6.5 with a sodium phosphate gradient<sup>9</sup>. The total radioactivity in  $\alpha$ ,  $\beta$ S and  $\beta$ A globin peaks was summed when these chains were present in the sample, and was divided by the  $\alpha$ -globin peak to obtain the non- $\alpha/\alpha$  ratio.

loci, such as those with sickle cell disease and thalassaemia major.

We thank Robert Weierbach for technical assistance, Janet Fithian for help with the manuscript, and Drs T. H. J. Huisman and W. A. Schroeder for determination of the glycine residues at  $\gamma^{136}$ . This work was supported in part by grants and a contract from the US Public Health Service, a contract from the Commonwealth of Pennsylvania, and a grant from the Cooley's Anemia Fund, Inc.

## Permeability of the blood-cerebrospinal fluid barrier to plasma proteins during foetal and perinatal life

HIGH levels of alpha foetoprotein (AFP), albumin and IgG have been detected in the cerebrospinal fluid (CSF) of six human foetuses between 16.5 and 25 weeks old<sup>1</sup>. The levels of AFP were found to decline from 1,200  $\mu\text{g ml}^{-1}$  in a foetus of 16.5 weeks to 52 and 60  $\mu\text{g ml}^{-1}$  in the older ones tested. During this period of foetal life, the ratios between albumin and AFP in CSF were shown to increase. The levels of IgG ranged between 60 and 117  $\mu\text{g ml}^{-1}$  and were higher than those detected in CSF from normal adult subjects (20-40  $\mu\text{g ml}^{-1}$ )<sup>2</sup>.

These preliminary results have prompted us to extend our investigations to CSF from a larger group of human foetuses and compare the levels of albumin, AFP and IgG with those of total protein, transferrin,  $\beta$ -trace protein<sup>3,4</sup>,  $\beta$ 2-microglobulin<sup>5</sup> and lysozyme<sup>6</sup>. Samples of CSF were obtained from 13 foetuses between 14 and 25 weeks old and one sample from a foetus 40 weeks old with hydrocephaly and severe achondroplasia (Table 1). Some of these foetuses were obtained by hysterotomy and had chromosome abnormalities; others were aborted spontaneously and apparently normal. One was a male foetus obtained by therapeutic abortion from a woman carrier of a gene for haemophilia.

CSF was collected by aspiration with a syringe from the cisterna magna; only CSF samples which were absolutely clear from contamination by blood were tested.

The levels of albumin, transferrin, IgG and  $\beta$ -trace protein were estimated by the single radial diffusion technique<sup>7</sup>; AFP was measured by the one dimensional antigen-antibody electrophoresis (rocket technique)<sup>1</sup>; lysozyme by

the lysoplate method<sup>8</sup> and the levels of  $\beta$ 2-microglobulin by radioimmunoassay (Phadebas,  $\beta$ 2-microtest, Pharmacia).

The levels of AFP were higher in CSF of foetuses less than 20 weeks old than in the older foetuses; in two foetuses 16.5 and 19 weeks old the levels were more than 1  $\text{mg ml}^{-1}$ , whereas in three foetuses 25 weeks old the values of AFP varied between 17 and 52  $\mu\text{g ml}^{-1}$  (Table 1). In the 40-week-old foetus, the concentration of AFP in CSF was less than 1  $\mu\text{g ml}^{-1}$ . The levels of albumin and the ratios of albumin to AFP were higher in foetuses between 20 and 25 weeks old than in the younger foetuses (Table 2). Ratios between 1.8 and 4.7 were observed when the levels of total proteins and those of albumin were compared.

IgG was detected in all foetuses studied and slightly higher levels were observed in samples from foetuses between 20 and 25 weeks old.  $\beta$ 2-Microglobulin was found in all samples tested (Table 1) and the ratio IgG/ $\beta$ 2-microglobulin showed only minor variations, ranging between 48 and 116 (Table 2). Lysozyme could not be detected in the foetal CSF using the lysoplate technique;  $\beta$ -trace protein, was found in all foetal CSF and appeared to be a major protein of this body fluid.

In summary, all the proteins tested, with the exception of lysozyme, have been found in foetal CSF in concentrations much higher than those detected in CSF from normal adult subjects. These results, therefore, support the suggestion that the human blood-CSF barrier is not fully developed during foetal life<sup>1</sup> and explain the detection of the high levels of IgG and the presence of specific maternal antibodies in CSF of human infants tested during the first weeks of life<sup>8-10</sup>.

The presence of high levels of AFP in foetal CSF also supports the view that the increased amount of this foetal protein detected in the amniotic fluids of foetuses with open neural-tube defects is due to the transfer of AFP from CSF into the amniotic cavity<sup>1,11,12</sup>.

In view of the high levels of proteins detected in CSF from human foetuses, the transfer of labelled proteins from the blood to the CSF was investigated in newborn and adult rats (M.A. and S.H.). Albumin and IgG were isolated from adult rat serum by precipitation with ammonium sulphate, DEAE chromatography and gel filtration on Sephadex G-200 (ref. 7). Rat IgG antibodies against brain antigens were isolated, using similar techniques, from an immune serum given by Dr R. Hughes, Guy's Hospital Medical School. <sup>14</sup>C-Oestrogen was purchased from the Radiochemical Centre (4-<sup>14</sup>C-oestradiol, 10  $\mu\text{Ci}$  per 510 ml).

Rat albumin, and rat IgG from normal rat serum and immune serum were labelled with <sup>125</sup>I (specific activity 14  $\text{mCi mg}^{-1}$  iodine, Amersham) using the chloramine T method<sup>13</sup>. The extent of <sup>125</sup>I incorporation was assayed after precipitation of the labelled proteins—in the presence of carrier protein—with 10% trichloroacetic acid (TCA) and by the analysis of radioactivity in strips obtained from cellulose acetate electrophoretic patterns, as previously described<sup>14</sup>.

The labelled proteins were injected into the peritoneal cavity of newborn rats, on the first, third, fourth and seventh day after birth. The newborn animals—and the adult rats, used as controls—were killed between 3 and 24 h after the injections and blood was collected from the jugular vein. Samples of CSF, free of blood, were collected from the cisterna magna<sup>15</sup>.

In the 1-d-old rats about 20 and 10% of <sup>125</sup>I-albumin and <sup>125</sup>I-IgG, respectively present in blood, were detected in CSF 3 h after the injections into the peritoneal cavity. The labelled proteins could not be detected in CSF obtained from rats 7 d old or from adult rats, 3 h after the injections.

Figure 1 shows the results of one of the experiments in which <sup>125</sup>I-IgG isolated from normal rat serum or from rat immune serum containing antibodies against rat brain antigens, were used. Two newborn rats were injected intra-peritoneally with <sup>125</sup>I-IgG and two newborns with <sup>125</sup>I-IgG

rat anti-rat brain. After 3 h the animals were killed and the radioactivity was measured in blood and CSF. Another four newborn rats from the same litter were injected when 4 d old and the remaining three at 7 d of age. About 10% of <sup>125</sup>I-IgG present in blood was detected in the CSF from 1-d-old rats. In the newborn rats injected with rat IgG antibodies against brain antigens the CSF contained over 20% of the labelled protein present in blood. Higher values of labelled IgG were detected in the CSF of rats 4 d old injected with rat antibodies than in rats injected with normal IgG. In rats 7 d old, less than 1% of the labelled protein present in blood was detected in the CSF of the animals killed 3 h after injection (Fig. 1).

More than 96% of the radioactivity present in serum and CSF was precipitated by TCA. When these samples were analysed by cellulose acetate electrophoresis, the peaks of radioactivity in serum and CSF were detected in the area corresponding to the IgG region in the electrophoretic patterns.

Preliminary studies have also indicated that an equilibrium between the levels of radioactive albumin or IgG in blood and CSF is reached within 24 h of the intraperitoneal injection into 1-d-old rats.

<sup>14</sup>C-Oestradiol, injected intraperitoneally in newborn rats, was detected in CSF 4 h after injection; the amount of labelled hormone found in CSF was between 40 and 60% of that detected in blood.

These studies and the results of preliminary investigations using heterologous antibodies against rat brain antigens (M.A. and S.H.) have thus confirmed that the permeability of the blood-CSF barrier is not fully developed during foetal and perinatal life in man and rats<sup>1,16</sup>.

It has long been recognised that the development of brain and unfolding of behaviour are sensitive to modifications by environmental factors<sup>17</sup>.

Experimental studies, reviewed by Balazs<sup>18</sup>, have shown that abnormal hormonal states during foetal life can result in permanent behavioural disorders, whereas, in adults, they usually induce changes that are reversible.

We suggest that, in abnormal maternal states, the permeability of the foetal blood-CSF barrier to hormones and antibodies against antigens of the nervous system may have an important role in the production of long lasting damage to the developing brain and to the unfolding of behaviour. Experimental work in progress should confirm or disprove this hypothesis.

This work was supported by the Spastics Society and the MRC. We thank Mrs Susan Embury and Mr C. Malloni for technical help and Professor C. A. C. Mims for advice on collecting CSF from rats.

## Antibodies to native tRNA in NZB/NZW mice

ANTIBODIES to native DNA, double-stranded RNA, and various synthetic polyribonucleotides occur with great frequency in patients with systemic lupus erythematosus (SLE)<sup>1</sup>. These antibodies are also present in the New Zealand mouse, particularly the NZB/NZW F<sub>1</sub> hybrid,

which is considered a good animal model for human SLE<sup>2</sup>. We report here the presence and characterisation of antibodies that bind tRNA, specifically in its native conformation, in sera from old NZB/NZW mice.

Figure 1 shows the results of gel chromatography experiments that demonstrate the presence of anti-tRNA antibodies in old NZB/NZW female mouse serum. The serum was treated to eliminate ribonuclease activity, incubated with radioactive *E. coli* tRNA, and then chromatographed on a small column of Sephadex G-100. Protein-bound tRNA was excluded from the gel while unbound tRNA was retarded (Fig. 1b). Control mice serum showed virtually no binding (Fig. 1a). We could also demonstrate tRNA binding activity in the NZB/NZW sera, but not in controls, using ammonium sulphate precipitation<sup>3</sup> or by precipitation of the complex with a rabbit anti-mouse antibody preparation.

**Fig. 1** NZB/NZW  $F_1$  hybrids and BALB/c control strains were obtained from colonies maintained at the National Institutes of Health. Mice were bled by orbital sinus puncture. About 20 sera were pooled, heated to 56 °C for 30 min and the immunoglobulin fraction was precipitated by  $(\text{NH}_4)_2\text{SO}_4$  at 50% saturation. This fraction was treated with charcoal to remove ribonuclease activity (manuscript in preparation) and then dissolved in phosphate-buffered saline to the volume of the original serum. Reaction mixtures contained 0.1 ml of serum, 0.15  $\mu\text{g}$  (2,000 c.p.m.) of *E. coli*  $^3\text{H}$ -tRNA (obtained by growing bacteria in medium containing  $^3\text{H}$ -uridine), and 0.01 M  $\text{MgCl}_2$  in a final volume of 0.12 ml. The mixture was incubated for 1 h at 4 °C and then applied to a  $0.7 \times 30$  cm Sephadex G-100 column. Chromatography was at 4 °C. Fractions of 0.65 ml were collected, measured for absorbance at 280 nm and counted in a scintillation counter. *a*, Incubation of  $^3\text{H}$ -tRNA with normal serum; *b*, incubation of  $^3\text{H}$ -tRNA with 8-month-old NZB/NZW female mouse serum.  $\circ$ ,  $A_{280}$ ;  $\bullet$ ,  $^3\text{H}$ -radioactivity.

Figure 2 shows the capability of the serum to bind essentially all added tRNA, indicating that the antibody recognises a general feature of all native tRNAs and not one or more of the rare nucleosides. (Alternatively, there may be subpopulations of antibodies which recognise each amino acid-specific tRNA.) Studies of antibodies made to conjugated yeast phenylalanine tRNA showed that they recognised only a modified nucleoside in the tRNA<sup>4</sup>. Figure 3 shows the age dependence of tRNA binding activity in the sera of female NZB/NZW mice. Each point represents the binding activity of sera pooled from 20 mice. The abrupt increase in binding at between 5 and 7 months suggests that these hybrid mice are programmed genetically

**Fig. 2** Binding curve of  $^3\text{H}$ -tRNA to 8-month-old NZB/NZW mouse female serum. Increasing amounts of serum were incubated with a fixed amount (75 ng) of  $^3\text{H}$ -tRNA. Binding capacity was measured by Sephadex chromatography as described in the legend to Fig. 1.

to produce anti-nucleic acid antibodies at a particular age. The production of anti-tRNA antibodies is very well correlated with other manifestations of the sickness<sup>2</sup>, such as renal immunoglobulin deposition, renal histological abnormalities, proteinuria and the production of anti-DNA antibodies<sup>5</sup>. The decline in tRNA binding activity after 10 months of age may result from the death of the most severely ill animals, decreased production or increased catabolism of the antibodies<sup>2</sup>.

NZB/NZW female mice (8–9 months old) sera were also assayed individually for tRNA and DNA-binding activity. All sera that bound DNA were also positive for tRNA. Five out of seven selected on the basis of very low double-stranded DNA binding (indistinguishable from normal mice), however, showed substantial binding for tRNA as well as for single-stranded DNA. These results suggest that anti-tRNA antibodies are more characteristic of old NZB/NZW mice than anti-native DNA antibodies.

Since the tRNA-binding protein in old NZB/NZW mouse serum is produced spontaneously in pathological conditions and not in response to a given immunogen, we tried to demonstrate that this protein is an immunoglobulin

**Table 1** Inhibition of  $^3\text{H}$ -tRNA and  $^{14}\text{C}$ -DNA-binding to NZB/NZW sera by nucleic acids and nucleic acid components

Inhibitor	Inhibition of $^3\text{H}$ -tRNA-antibody complex (%)	Inhibition of $^{14}\text{C}$ -DNA-antibody complex (%)

Denatured MS2 viral RNA	13	20
16S ribosomal RNA	41	35
5S ribosomal RNA	43	26

$^3\text{H}$ -tRNA (0.15  $\mu\text{g}$ ) or native KB cell  $^{14}\text{C}$ -DNA<sup>6</sup> (0.05  $\mu\text{g}$ ) were mixed with 1.5  $\mu\text{g}$  of each of the specified inhibitors and NZB/NZW serum (100  $\mu\text{l}$  serum for the  $^3\text{H}$ -tRNA assay and 10  $\mu\text{l}$  serum for the  $^{14}\text{C}$ -DNA assay). Incubation was for 60 min at 4 °C. tRNA binding was analysed by Sephadex chromatography, as described in the legend to Fig. 1. DNA binding was measured by ammonium sulphate precipitation at 35% saturation. Denatured tRNA and denatured MS2 RNA were prepared by the method of Axelrod *et al.*<sup>13</sup>. MS2 RNA was given by Dr Rushizky, National Institutes of Health.

and not another binding protein or an enzyme. We used a multivalent rabbit anti-mouse  $\gamma$  globulin which had been purified by affinity chromatography (given by Dr R. Asofsky). Addition of 0.6 mg of this immunoglobulin to 50  $\mu$ l of the NZB/NZW serum, incubation at 4 °C for 5 d and centrifugation decreased the subsequent binding activity for  $^3$ H-tRNA by 96%. Furthermore, the purified anti-mouse  $\gamma$  globulin could precipitate all the tRNA bound to NZB/NZW serum in 2 h at 4 °C.

The specificity of old NZB/NZW mouse serum with respect to different nucleic acid antigens was tested by competition experiments (Table 1). The same antigens were also used to inhibit complex formation between anti-DNA antibodies and native  $^{14}$ C-DNA. The antibodies in NZB/NZW serum that bound tRNA and DNA behaved as distinct antibody populations, as the inhibition patterns of the two populations by different nucleic acids were very different (Table 1).  $^3$ H-tRNA binding was best inhibited by tRNA while  $^{14}$ C-DNA binding was best inhibited by double-stranded and single-stranded DNA.

Fig. 3 About 20 female NZB/NZW mice of each age were bled and the sera were pooled, and assayed for tRNA-binding activity by Sephadex chromatography as described in Fig. 1.

Rat liver tRNA inhibited the tRNA-antibody reaction to the same extent as did *E. coli* tRNA. This supports the contention that the antibodies recognise a general feature in the structure of tRNA and not minor components which are somewhat different in the two species.

On the other hand, denatured tRNA which was fixed in its denatured conformation by formaldehyde, did not effectively compete with native tRNA, so this serum shows a marked specificity for the native conformation of tRNA. Nucleosides and nucleotides did not inhibit the binding reaction at all. The double-stranded synthetic polynucleotide poly(rI)-poly(rC) and DNA, which both bind very well to sera of NZB/NZW mice and SLE patients<sup>6</sup>, inhibited tRNA-binding to a very small extent. Conversely, single-stranded viral RNAs and ribosomal RNAs, which are believed to form hairpin secondary structures similar to those of tRNAs<sup>7,8</sup>, competed fairly effectively. In fact, 5S rRNA has been shown to compete with tRNA for a ribosomal binding site<sup>9</sup> and some viral RNAs can be aminoacylated by aminoacyl tRNA synthetases<sup>10</sup>. Denatured MS2 RNA cross linked with formaldehyde was a poor inhibitor compared with native MS2 RNA.

Attempts have been made in many laboratories to elicit antibodies specific for tRNA in experimental animals<sup>11,12</sup>. None of these antibodies has shown evidence of specificity for the secondary or tertiary conformation of the tRNA. Such antibodies would be useful for studies of the conformation and function of free and complexed tRNA in solution. The antibodies in the sera of the NZB/NZW mice may be useful in this connection and they should be

of value in understanding the molecular basis of lupus-like diseases.

## Genetic control of type C virus of wild mice

THE genetic control of type C virus group-specific (GS) antigen expression<sup>1,2</sup>, infectious virus<sup>3-6</sup>, and tumorigenesis<sup>6,7</sup> has been described in crosses between strains of inbred laboratory mice with high and low incidence of leukaemia. We described a natural population of wild mice (*Mus musculus*) near Lake Casitas (LC) in southern California which showed a high level of indigenous type C virus activity in terms of GS antigen and infectious virus throughout their lifetime. When ageing was observed in the laboratory, LC wild mice showed a marked susceptibility to lymphoma<sup>8</sup>, epithelial tumours<sup>9</sup> and a neurogenic hind leg paralysis<sup>10</sup>. Virus transmission and *in vivo* neutralisation studies<sup>11</sup> established the indigenous type C virus as the critical determinant of the lymphoma and paralysis. To ultimately prevent these diseases by antiviral measures we have attempted to suppress LC virus expression by cross-breeding LC wild mice with a specific inbred laboratory mouse strain C57BL/10 Snell (designated B10). The B10 mouse was selected because of its homozygosity for two non-linked dominant alleles, *Fv-1<sup>b</sup>* and *MLv-1<sup>b</sup>*, the function of either of which might be expected to restrict virus expression in the hybrid progeny. Laboratory strains of mouse type C virus can be classified according to their *in vitro* host range as N-, B-, or X(xenotropic)-tropic depending on whether they grow preferentially in NIH Swiss or BALB/c embryo cells or replicate only in non-murine cells<sup>12,13</sup>. Field isolates from LC mice have an unusually wide *in vitro* host range ('amphotropic') but are N-tropic for mouse cells (S. Rasheed, V.K., and M.B.G., unpublished). B10 mice, within the first year of life, show a low incidence of both N- and B-tropic infectious virus<sup>14</sup> and also harbour an endogenous X-tropic genome<sup>15</sup>. The *Fv-1<sup>b</sup>* allele from the B10 parent should limit the replication of N-tropic virus within the LC×B10 progeny<sup>15</sup>, presumably by interfering with the integration or transcription of the proviral DNA<sup>16</sup>. The *MLv-1<sup>b</sup>* allele, the function of which is unknown, might restrict either N-, B-, or X-tropic virus expression in the progeny since this allele completely suppressed GS antigen expression in B10 crosses with the

congenic resistant (58N) strain<sup>17</sup>. Although the genetic mechanism has yet to be established, our findings indicate that control of type C virus expression can be accomplished by genetic means in wild mice.

Parental 6-month-old B10 mice (Jackson Laboratory) were reciprocally bred with newly trapped LC wild mice. Based on their weight of 10–15 g the LC parental mice were estimated to be 6 months old. A laboratory breeding colony of LC mice was also established. Parental mice were splenectomised before breeding and the segregating progeny from the various crosses (Table 1) were splenectomised at 4–6 weeks of age. Spleen extracts (10% w/v) were tested for GS (p30) antigen by the complement fixation (CF) test. Six male and five female LC mice whose spleens were positive for GS antigen were selected for the parental mating with separate B10s. All the parental and backcross B10 mice showed an absence of detectable spleen GS antigen.

The segregation of GS antigen expression in the different crosses is shown in Table 1. In striking contrast to the high prevalence and titre of detectable spleen CF GS antigen in the LC parental (72.6% GS positive, 49.5%  $\geq 1:4$ ), and 4–6-week-old LC mice born in the laboratory (66.7% GS positive, 40.0%  $\geq 1:4$ ), there was an almost complete absence of detectable spleen GS antigen in the 4–6-week-old reciprocal LC $\times$ B10 F<sub>1</sub> hybrids (1.4%) and in the reciprocal F<sub>1</sub> (2.3%) and F<sub>2</sub> (1.7%) B10 backcrosses. The negligible occurrence of detectable GS antigen at weanling age in the F<sub>1</sub> hybrids and B10 backcross progeny indicates a dominant negative effect on this form of viral expression.

To determine if suppression of GS antigen expression was temporary or long lasting, we tested 10% extracts for

**Table 2** Type C virus isolation from wild-inbred parental and hybrid mice

Generation or cross	Spleen CF GS positive		Spleen CF GS negative	
	Spleen	Tail	Spleen	Tail
B10 parental	—	—	1/10	1/5
LC parental	4/4	3/5	—	—
F <sub>1</sub>	1/2	0/2	0/10	1/10
F <sub>2</sub>	1/13	0/10	0/24	0/10
F <sub>1</sub> backcross B10	1/1	0/5	0/9	0/5
F <sub>1</sub> backcross LC	9/9	4/6	0/9	0/2

For virus isolation 0.1 ml 10% spleen extract (stored at  $-70^{\circ}\text{C}$  for several months) and 0.1 ml fresh 20% tail homogenates (not necessarily from the same individual mice) were assayed undiluted for induction of CF GS antigen after 21 d (COMUL test) on wild mouse SC-1 (ref. 20) and rabbit SIRC<sup>21</sup> cells. Antisera used were as in Table 1.

CF GS antigen from a random sample of healthy F<sub>1</sub> progeny and F<sub>1</sub> backcrosses to B10 progeny after various periods of observation. We have shown that in 3-week-old LC mice, the degree of type C virus expression in the liver is equal to that in the spleen (M.B.G., V.K. and R.J.H., unpublished). GS antigen was detected in none of 23 F<sub>1</sub> hybrids and 93 F<sub>1</sub> backcross to B10 progeny observed for an average of 7 months (range 3–10 months). The repression of GS antigen thus seemed fairly long lasting.

In the F<sub>2</sub> reciprocal crosses, spleen GS antigen was found in an average of 10.0% (range 3.7–17.6%), mostly in low titre (1:2), (Table 1). Although these results suggested a two gene suppressive effect on GS antigen expression which would have predicted 7% GS antigen positive in the F<sub>2</sub> generation, we could not confirm this hypothesis by analysis of the GS antigen ratios in the F<sub>1</sub> backcross to LC mice. A greater prevalence of spleen GS antigen was observed in backcross matings with LC females (average 42.0%) compared with LC males (average 14.8%), (Table 1). This finding suggested either a positive maternal effect on virus expression by epigenetic spread of virus to offspring from the heavily infected LC maternal reproductive tract (M.B.G., V.K. and R.J.H., unpublished) and milk<sup>18</sup> or a negative maternal effect, presumably from neutralising antibodies passed to their offspring by the virus-antigen-stimulated hybrid mothers<sup>4</sup>. In the latter instance the only segregation data that would be directly interpretable are those backcross matings with LC mothers. Viewed in this way our results are most compatible with segregation of a single gene, that is, 42% observed compared with 50% predicated GS-positive progeny in the LC maternal backcross. The single gene probably responsible for this suppression of GS antigen would be the *Fv-1* rather than *MLv-1<sup>b</sup>* since the *Fv-1* locus has been shown to be the major determinant of virus expression and spontaneous leukaemia in hybrids with AKR and other high-leukaemia *Fv-1<sup>a</sup>* laboratory mouse strains<sup>4,6</sup>. A more extensive genetic analysis will be required, however, to rigorously establish the gene locus primarily responsible for this dominant control of virus expression in LC wild mice.

A sample of the 10% spleen extracts collected at 4–6 weeks of age and previously tested for GS antigen by CF, and fresh 10% tail clip homogenates collected at 6–12 months of age were assayed for infectious virus by the COMUL test<sup>19</sup> on mouse (SC-1) and rabbit (SIRC) cells (Table 2). SC-1 cells (Dr J. Hartley, NIAID, NIH) are a cloned wild mouse embryo cell line which seem to lack both the *Fv-1<sup>a</sup>* and *Fv-1<sup>b</sup>* alleles and are thus equally susceptible to N- and B-tropic viruses<sup>20</sup>. SIRC cells are a rabbit cell line<sup>21</sup> susceptible to the X-tropic viruses of laboratory mice and the amphotropic viruses from LC wild mice (S. Rasheed, V.K., and M.B.G., unpublished). Virus was recovered in both SC-1 and SIRC cells from all the high titred ( $\geq 1:4$ ) GS-positive spleens (13 of 13) and from most (7 of 11) of the tail homogenates tested from the parental and backcross LC mice. By contrast,

virus was recovered in only SC-1 cells from just 6 of 116 total assays from spleen and tail of parental B10 and F<sub>1</sub>, F<sub>2</sub>, and B10 backcross progeny, including a sample from those few mice in these groups whose spleen extracts were weakly positive (1:2) for CF GS antigen. Thus, infectious amphotropic virus could readily be recovered from spleen or tail only of parental and backcross LC mice which had high titred spleen GS antigen. In no instance was virus isolated on SIRC and not on SC-1 cells. Therefore, it is unlikely that any of the other isolates represented the X-tropic class of endogenous type C virus. Suppression of GS antigen expression in LC × B10 hybrids was clearly correlated with a suppression of infectious type C virus production.

Observation of (LC × B10) F<sub>1</sub>, F<sub>2</sub> and backcross progeny into old age is now under way to determine if resistance to lymphoma, epithelial tumours, and paralysis will occur in those hybrids segregating for lack of GS antigen and infectious virus expression.

We thank Drs Ben Taylor, Hans Jorg-Heiniger and Wallace Rowe for advice, and Messrs Michael Hejjas, John Casagrande and Angel Chiri for assistance. Supported by the National Cancer Institute.

## Second genetic locus in the HLA region for human B-cell alloantigens

THE ability to separate human peripheral blood T and B lymphocytes has allowed serological identification of specific B cell antigens, and several lines of evidence indicate that these antigens are controlled by a gene or genes of the HLA genetic region<sup>1</sup>. Van Rood *et al.* presented evidence for an antigen which seems to be associated with, or closely linked to, the

locus responsible for mixed lymphocyte stimulation (HLA-D)<sup>2</sup>. Our results in family studies suggest that there are a number of specific B-cell alloantigens that are controlled by genes linked closely to genes controlling the expression of HLA alloantigens<sup>3,4</sup>.

B-cell alloantigens have been defined in murine systems and have been designated Ia antigens, which seem to be controlled by genes mapping within the H-2 complex<sup>5</sup>. At least three genes have now been identified controlling the different Ia antigens<sup>6</sup>. If the genetic region controlling cell-surface antigens on lymphocytes is analogous in the murine and human species, it seems probable that several genes might control the expression of human B-cell alloantigens. The results, presented here, of studies on B-lymphocyte antigens in a family where one member was an HLA recombinant provides evidence that such is the case.

We used human sera containing antibodies detecting B-cell specific antigens, obtained from multiparous women of a religious sect, the Amish, who, for cultural and religious reasons, live in rather isolated communities and, as a result, marry exclusively within the community. Peripheral blood lymphocytes were obtained from the father, mother and six children from the Amish family under study.

T and B lymphocytes were separated as previously described<sup>4</sup> and tested by cytotoxicity with 34 antisera that were known to detect specific B-cell antigens and which did not react with HLA alloantigens. Briefly, this technique for separation and typing is as follows. Peripheral blood lymphocytes were isolated from heparinised whole peripheral blood by sedimentation with Ficoll-Hypaque, macrophages were depleted with carbonyl iron, and  $2 \times 10^5$  lymphocytes were dispensed into microtitre plates that had been coated with antigen-antibody complexes. The lymphocytes were allowed to settle, resulting in adherence of the cell population bearing Fc receptors. The plates were then flooded, inverted, and the non-adherent cells recovered, concentrated, and  $10^3$  cells dispensed into microtitre plates for testing against the same sera that were used to test the adherent cell population. The adherent and the non-adherent cells were tested in triplicate with each of the 34 antisera and appropriate controls consisting of normal human sera and a known lymphocytotoxic sera. Whole rabbit serum was used as a source of complement.

Antiserum (5 µl) was allowed to incubate with the cells for 1 h, the cells were washed with balanced salt solution containing 10% heat-inactivated foetal bovine serum and 5 µl of complement added. After incubation the complement was removed, the cells washed, and 5 µl of complement added for an additional 1-h incubation period. Complement was then removed and Trypan blue added. The reaction was deemed cytotoxic positive when > 30% of the cells (over that seen in the negative controls) incorporated Trypan blue. The background in negative controls was within the range 0–10% cells stained.

The results of the B-lymphocyte typing in this family are shown in Table 1 together with the HLA genotype of each family member. The serum reactivity reported here showed exclusive reactivity with B cells and no activity against the non-adherent or T-cell population. All the antisera can be assigned to HLA haplotypes and seven can be assigned to genetic subregions within the haplotype. Serum 640 was the unique marker for the maternal 1–8 haplotype inherited by sib 5. Sera 289 and 43 reacted against markers for the maternal 3–7 haplotype inherited by sibs 1, 2, 3, 4 and 6. Sera 35, 76, and 177 defined the 1–12 paternal haplotype inherited by sibs 3 and 4 and sera 590, 67, 322, 251 and 370 were directed against the 9–27 haplotype inherited by sibs 1, 2 and 5. Sib 6 was known from previous HLA typing to be a recombinant between the HLA-A and HLA-B loci. His cells were reacted against by sera 289 and 43, and by 35, 76, 322, 251 and 370. The reactions of 289 and 43 are clearly against the 3–7 haplotype. Reactions of sera 35 and 76 are shared with those sibs possessing HLA-A2 and are thus directed against an HLA-A region product. Sera 322, 251

\*Three large families were tested for B lymphocyte antigens. Listed above are the HLA haplotypes found in these families and the reactions of their cells with the B-cell typing sera.

and 370 react with the HLA-B region product as shown by reactions of sibs 1, 2, 5 and 6. Note that sib 6 is not reactive with sera 590 and 67 associated with the intact 2-12 haplotype. This failure to react is not an artefact, as shown by absorption studies. Sera 177, 590 and 67 were absorbed with cells from sib 6 and retested against cells from the father. All remained fully active, showing that the antigens were indeed absent from the recombinant.

This shows clearly that the B-cell antigens are coded for by at least two genetic loci, one associated with the HLA-A portion of the haplotype and one with the HLA-B portion. This family study is not informative as to the precise location of the genes within the HLA-A and HLA-B regions. We can, however, be fairly sure that the genes for B-cell antigens are separate from the determinants for HLA-A and HLA-B from three lines of evidence. First, the sera react only against B cells; their failure to react against T cells argues against their being antibodies to the A, B, or C loci of HLA. Second, serum 590 was produced in a woman HLA 3-7/28-14 against a husband 3-7/3-BW55, so cannot react with HLA-A9, and a similar argument can be made for antiserum 67. The serum donor was 2-BW35/28-27 and her husband 2-7/11-27. Third, when tested on a random panel of B cells from subjects characterised for HLA, the antisera did not correlate with the distribution of HLA specificities. Further, when the reactions of the sera were examined in other families, different patterns of reactivity were observed. For example, in one family 590 reacted together with sera 177 and 176 to define the 2-7 haplotype in a group of nine sibs and in another family serum 177 reacted with four sibs inheriting the 9-BW15 haplotype whereas 590 reacted

with five sibs inheriting the 29-BW40 haplotype (Table 2). Thus not only do the different anti-B-cell sera sort with different HLA haplotypes in different families, they also seem to detect different B-cell specificities.

The present evidence indicates that there is a minimum of two loci for B-cell antigens within the HLA region. From the reactions of HLA haplotype-associated B-cell antisera in different families it seems probable that this is a minimum estimate and that the number of genetic loci may be considerably higher.

## Electron transfer across membranes using vitamin K<sub>1</sub> and coenzyme Q<sub>10</sub> as carrier molecules

CONTINUOUS redox processes have been effected between aqueous reactants, separated by liquid membranes in which coenzyme Q, or vitamin K, is present as a carrier molecule. These membranes show chemical specificity and function which relate closely to certain biological electron transfer processes.

The neutral lipid, coenzyme Q, is an essential link in the electron-transfer chain in mitochondria, and vitamin K may have a similar function in chloroplasts and certain bacteria.

We investigated the conditions in which these amphipathic quinone lipids may act as electron transfer agents, using solutions of vitamin K<sub>1</sub> and coenzyme Q<sub>10</sub> in hydrocarbon solvents as liquid membranes. These bulk membranes, being less dense than water, separated aqueous reducing agents and potentially reducible substrates (Fig. 1). The membranes may be considered to be composed of three parts; two interfacial monolayers, in which hydrophilic quinone or quinol groups are present at the aqueous interfaces, and the bulk hydrocarbon solution phase. Since there is a dynamic equilibrium between the monolayers and the bulk membrane phase, molecules reduced on one side may be transferred by diffusion to the opposite interface where they may reduce the aqueous substrate (A in Fig. 1). When both reductant and substrate are insoluble in the membrane phase each quinol (reduced) molecule may act as a carrier for two electrons and two protons. Electro-neutrality is thus maintained in both aqueous phases and a continuous process of electron transport may be maintained.

The normal reduction potentials ( $E'_0$ ) for both vitamin K<sub>1</sub> and coenzyme Q<sub>10</sub> at pH 7 are close to 0 V (ref. 1) and so they are obtained in their oxidised forms in atmospheric conditions. To establish the requirements for a biphasic reduction, hexane solutions of quinone were equilibrated in oxygen-free conditions with various common aqueous reducing agents which had been shown to have no solubility in the hexane phase. Vitamin K<sub>1</sub> was reduced by only two reducing agents, methyl viologen and reduced flavin mononucleotide, FMNH<sub>2</sub>, (a prosthetic group of flavoproteins) both in phosphate buffer at pH 7. Coenzyme Q<sub>10</sub> was less specific and also was completely reduced by aqueous dithionite and borohydride ions. For vitamin K<sub>1</sub>, particularly, it seems that one-electron transfer agents are required. In support, electron spin resonance (ESR) spectra taken at the aqueous-liquid membrane interface during reduction with methyl viologen showed the presence of semi-quinone radicals as transient species for both quinones.

Of particular relevance to the role of coenzyme Q in natural membranes were the observations that, although aqueous solutions of NADH and NADPH were unable to reduce the

Fig. 1 Diagrammatic representation of the aqueous membrane model.

quinone directly, they may do so indirectly by a stepwise reduction involving FMN as an essential intermediate. These compounds, with their associated enzymes, have been shown to act in this sequence in the respiratory chain. Our results therefore indicate that limiting kinetic factors intrinsic to the electron-transfer process within the mitochondrion are already present in this simple analogue.

To establish continuous electron-transfer processes, experiments were conducted in an H cell, in which the quinone-hexane solution formed a liquid bridge between the two aqueous phases in the lower limbs of the cell. For convenience, reduced methyl viologen in phosphate buffer (pH 7) was used as reductant and various substrates were tested for reactivity. The apparatus was flushed with nitrogen and sealed. Equilibrations were conducted at 25 °C and the cell was vibrated gently to facilitate mixing in each of the three phases. Results, summarised in Table 1, show that a number of common redox indicators, used in biological studies on the respiratory chain, are completely reduced. Coenzyme Q<sub>10</sub> reduced ferric ion in acidic conditions and also iron III *o*-phenanthroline complex, which was reduced to ferroin. That cytochrome *c* was also completely reduced, indicated that these liquid membranes may be a suitable model for certain steps in the respiratory chain. Protonated molecules, such as reduced methylene blue, or protonated, oxidised, DCIP (the latter present to only 5% at pH 7) are soluble in hexane and are transported across the membrane. In mitochondria, this would provide a mechanism

Table 1 Tests of the reducing abilities of reduced vitamin K<sub>1</sub> and coenzyme Q<sub>10</sub> with a variety of common substrates

Substrate	$E'_0$ (ref. 1) (V)	$E_0$ (ref. 2) (V)	Reduced vitamin K	Reduced coenzyme Q	Comments
2,6-Dichlorophenol-indophenol	0.217		+	+	Back transfer of protonated (red) form
Indophenol	0.228		+		
Methylene blue	0.011		+	slight	Back transfer of reduced (leuko) form
Thionine	0.063		+	—	
FeCl <sub>3</sub>		0.77		+	
(Fe( <i>o</i> -phen) <sub>3</sub> )Cl <sub>3</sub>	1.12		+	+	Back transfer of uncomplexed <i>o</i> -phenanthroline
Cytochrome <i>c</i>	0.26		+	+	

The pH was maintained at 7 for each aqueous substrate except ferric chloride (which was in a solution of 0.1 M HCl) and the concentrations of the test solutions ranged from 0.01–0.10 mM.

of selective transport of molecules made lipid soluble by reduction or protonation.

Preliminary results have been obtained for the kinetics of reduction of aqueous substrates. The same H-cell format was used with the lower limbs (containing aqueous phases) replaced by optical cells. These aqueous limbs were stirred magnetically and turbulence and mixing of the quinone membrane solution obtained by gently rocking the whole apparatus. Tests showed that the rate of reduction of substrate was independent of whether or not the quinone was fully reduced at the start of the experiment. This confirmed that reduction by methyl viologen was rapid and that adequate agitation of bulk membrane had been obtained. Rates of transfer were insensitive to tenfold reduction in quinone concentration in the membrane, indicating a saturation effect typical of carrier-mediated transport. The reduction kinetics of methylene blue were first order with respect to the oxidised form and varied with stirring. These results are compatible with a diffusion-controlled mechanism, dependent only on the rate of diffusion of oxidised substrate from the bulk aqueous phase to the membrane interface. Electron transfer may thus be very rapid in this case.

Bimolecular lipid membranes have not been obtained, but stable thicker membranes  $\sim 1 \times 10^2$ – $3 \times 10^2$  nm have been formed in Teflon orifices using decane solutions of both quinones. These have been shown to function in the same way as the bulk membranes described above.

Apart from the obvious biological implications, such membrane systems provide a new sensitive method for the preparation and characterisation of solutions of reduced or oxygen-sensitive compounds, without the added complication of chemical contamination (other than protons required to ensure electroneutrality). In particular, solutions of pure reduced cytochrome *c* and of the very oxygen-sensitive reduced vitamin  $K_1$  in hexane were obtained in this study. The latter, previously uncharacterised, exhibited an intense maximum at 245 nm ( $\epsilon = 44,500$  l mol<sup>-1</sup> cm<sup>-1</sup>) and a broader weaker band at 325 nm.

We are grateful to Dr A. L. Porte for ESR measurements and to the Carnegie Trust and the SRC for maintenance grants to S.S.A. and I.G.L., respectively.

## Effect of experimental diabetes and insulin on phosphorylation of rat liver ribosomal protein S6

ONLY one rat liver ribosomal protein (S6) is phosphorylated *in vivo*<sup>1</sup>. During hepatic regeneration the phosphorylation of S6 is increased by an order of magnitude, and derivatives are generated (in some experiments as many as five) which contain increasing numbers of phosphoserine residues<sup>1</sup>. Very similar changes in the phosphorylation of S6 are caused by administration to animals of glucagon or cyclic AMP (A.M.G. and I.G.W., unpublished). Indeed, a number of hormones including adrenocorticotrophic hormone (ACTH)<sup>2</sup> and thyroid hormone<sup>3</sup> increase the phosphorylation of ribosomal protein, although in the latter instances, the identity of the phosphoprotein has not been established. These observations have led us to consider the possibility that cyclic AMP is the mediator of the phosphorylation of

S6 (ref. 4). The concentration of cyclic AMP in the liver is increased in diabetic animals and restored to normal by insulin<sup>5</sup>, although it is still moot whether the effect of the hormone on the level of the cyclic nucleotide accounts for all (or even any) of its actions on hepatic cells<sup>6</sup>. We have tested the effect of experimental diabetes and of insulin administration on the phosphorylation of rat liver ribosomal protein: the phosphorylation of S6 was markedly increased by diabetes, and reduced towards the normal level by insulin administration.

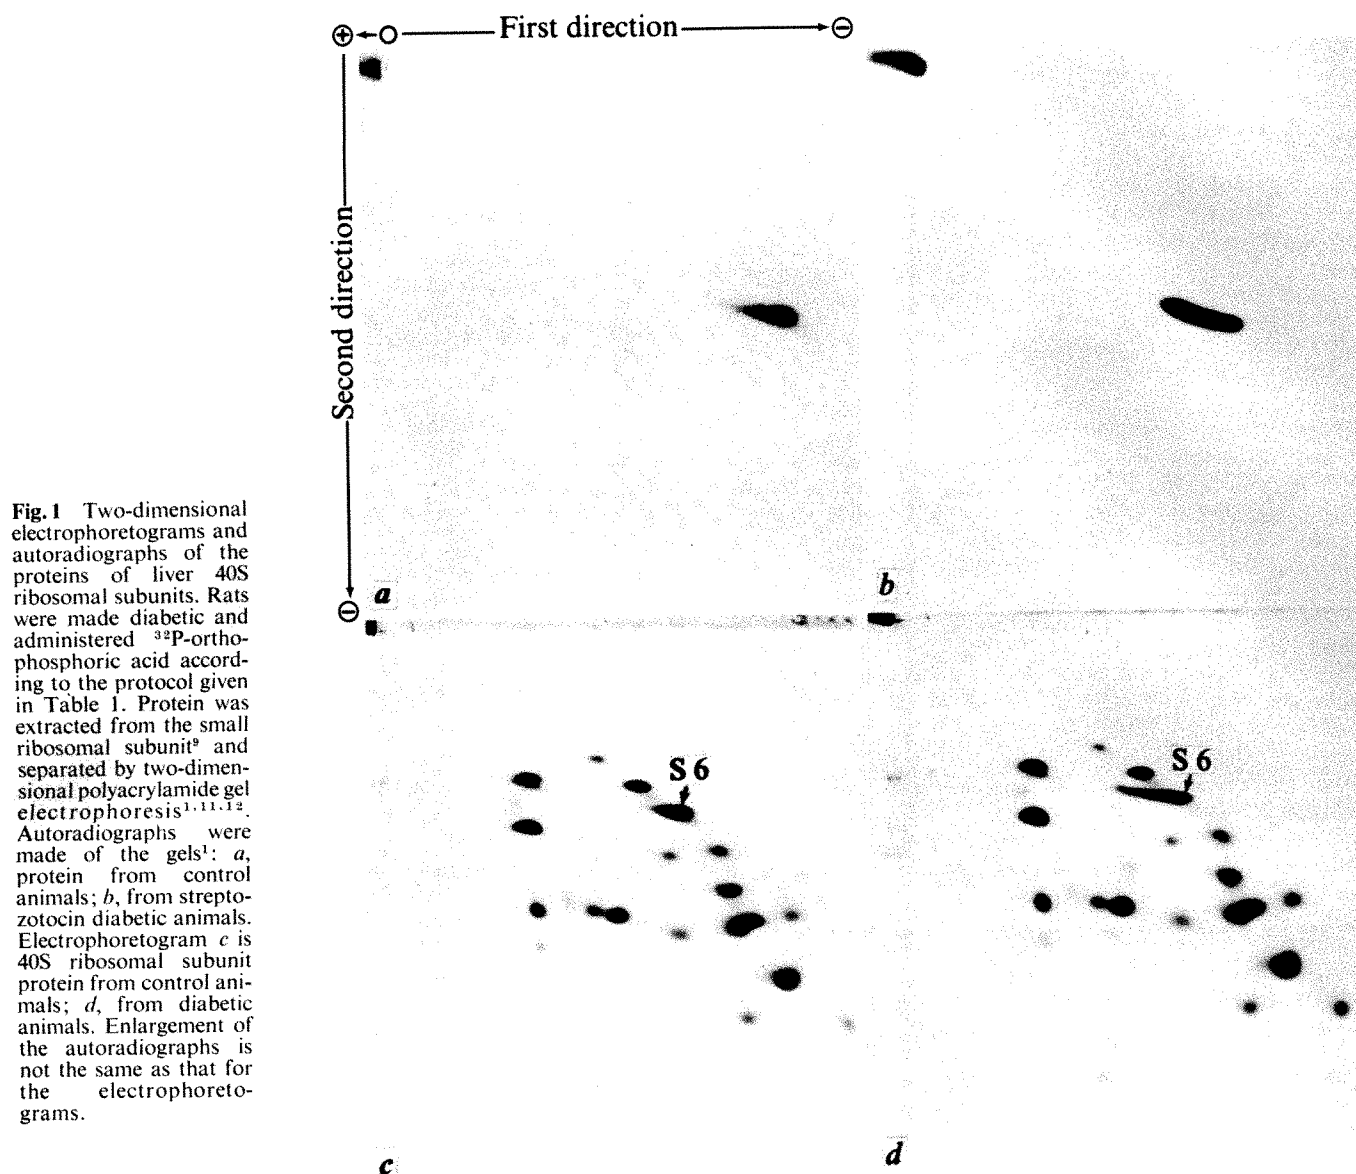

Diabetes caused a 3.5-fold increase in the <sup>32</sup>P-radioactivity associated with liver 80S ribosomes (Table 1); the administration of insulin (5 units per 100 g body weight) to diabetic animals reduced the radioactivity associated with the particles by about one-half in 90 min; phosphorylation, however, was not restored to normal during that period (Table 1). Not all of the radioactivity associated with liver ribosomes after administration of <sup>32</sup>P-orthophosphoric acid to rats is in ribosomal protein<sup>1</sup>. To test whether diabetes and insulin had actually affected the phosphorylation of ribosomal protein, subparticles were prepared from the ribosomes and the protein was extracted and the specific radioactivity determined. Diabetes increased the phosphorylation of the protein of the small ribosomal subunit by more than 3.5 times (Table 1); insulin administration decreased the specific <sup>32</sup>P-radioactivity of the protein of the 40S subparticle by somewhat less than one-half (Table 1). The effect of diabetes and insulin on phosphorylation of the small subunit protein can account for the alteration in radioactivity associated with 80S ribosomes. Very little radioactivity was in the protein of the large subunit and it was not appreciably changed by diabetes or insulin (Table 1). We have found<sup>1</sup> that phosphorylation of rat liver ribosomal protein *in vivo* is entirely in the 40S subunit; the radioactivity apparently associated with the large subunit is actually due to contamination with a small amount of 40S subparticles<sup>1</sup>.

All of the radioactive phosphate incorporated into rat liver ribosomes *in vivo* is found in S6 (ref. 1). It seemed likely, therefore, that it was the phosphorylation of S6 that was affected by diabetes and insulin. To test the possibility the proteins of the 40S subunit were separated by two-dimensional polyacrylamide gel electrophoresis and radioautographs made of the gels (Fig. 1). 40S ribosomal subunits from animals that had received <sup>32</sup>P-orthophosphoric

**Table 1** Incorporation of radioactivity from <sup>32</sup>P-orthophosphoric acid into rat liver ribosomes and ribosomal subunits

Source of liver ribosomes	<sup>32</sup> P-radioactivity		
	80S (c.p.m. per $A_{260}$ )	40S (c.p.m. per $\mu$ g protein)	60S (c.p.m. per $\mu$ g protein)
Normal	850	1.7	0.9
Diabetic	3,120	6.5	1.1
Insulin-treated diabetic	1,620	3.6	1.0

Male Holtzman rats (140–160 g) were starved for 24 h and injected intravenously with 65 mg per kg body weight of streptozotocin (lot no. 10518-GGS-37; provided by Dr W. E. Dulin, Upjohn) freshly dissolved in citrate buffer (pH 4.4). Control rats received the same volume of citrate buffer alone. Three days (68 h) after treatment with streptozotocin the fasting blood glucose levels were higher than 250 mg 100 ml<sup>-1</sup>. The diabetic animals were at that time divided into two groups of two or three rats each: one group received intraperitoneally 5 U crystalline porcine insulin (lot no. 615-063-10, containing 0.002% glucagon; provided by Dr O. Behrens, Eli Lilly) per 100 g body weight in saline. Control animals received a similar volume of saline. Animals (control, diabetic and insulin-treated diabetic) were injected intraperitoneally with 3 mCi <sup>32</sup>P-orthophosphoric acid (carrier-free, in 0.02 N HCl, 285 Ci mg<sup>-1</sup>, from ICN). Radioactive isotope was administered 90 min after animals received insulin or saline. All of the animals were decapitated 20 min after administration of the isotope. Livers were excised and ribosomes<sup>7</sup> and ribosomal subunits<sup>8</sup> prepared. Radioactivity in 80S ribosomal particles or in protein extracted from ribosomal subunits<sup>9</sup> was determined as described previously<sup>1</sup>. Concentration of protein in a sample was assessed<sup>10</sup> using bovine serum albumin as a standard.

**Fig. 1** Two-dimensional electrophoretograms and autoradiographs of the proteins of liver 40S ribosomal subunits. Rats were made diabetic and administered  $^{32}\text{P}$ -orthophosphoric acid according to the protocol given in Table 1. Protein was extracted from the small ribosomal subunit<sup>9</sup> and separated by two-dimensional polyacrylamide gel electrophoresis<sup>11,12</sup>. Autoradiographs were made of the gels: *a*, protein from control animals; *b*, from streptozotocin diabetic animals. Electrophoretogram *c* is 40S ribosomal subunit protein from control animals; *d*, from diabetic animals. Enlargement of the autoradiographs is not the same as that for the electrophoretograms.

acid, but no other treatment, had a single radioactive phosphoprotein (Fig. 1*a*). Comparison of the autoradiograph (Fig. 1*a*) and the stained two-dimensional gel (Fig. 1*c*) established that the protein was S6. Diabetes seemed to increase the specific radioactivity of S6 (Fig. 1*b*), although one could not be sure of that from the autoradiograph alone.

It was certain, however, that diabetes had changed the conformation of the protein. The zone containing S6 on the stained two-dimensional gel was elongated with a tail extending towards the anode (Fig. 1*d*); several (perhaps, as many as four) distinct derivatives of S6 could be discerned, each more negatively charged. Similar changes have been shown before<sup>1</sup> to be the result of phosphorylation of increased numbers of serine residues in the protein. The autoradiograph (Fig. 1*b*) conformed to that interpretation; the intensity of the zone described a gradient of specific radioactivity that was greatest in the anodal portion and least where one would expect the normal S6. Similar changes in S6 occur during hepatic regeneration<sup>1</sup>, as a result of the inhibition of protein synthesis with puromycin or cycloheximide<sup>4</sup>, and after administration of glucagon or cyclic AMP (A.M.G. and I.G.W., unpublished).

The increase in phosphorylation of S6 caused by diabetes cannot have been due solely to a change in the specific radioactivity of the intracellular pool of inorganic phos-

phate, or of ATP, as a result of a change in the transport of phosphate into hepatic cells. First, diabetes does not change the concentration of ATP in the liver<sup>12</sup>. But more important, one can see the highly phosphorylated derivatives of S6 on stained gels after two-dimensional electrophoresis of ribosomal protein from diabetic animals; they were not seen when ribosomal protein from normal animals was analysed. The demonstration of the derivatives of S6 on gel plates does not depend on changes in specific radioactivity and thus authenticates the enhancement of ribosomal protein phosphorylation as a result of diabetes.

Whether the change in S6, caused by insulin deficiency, is the result of increased phosphorylation or decreased dephosphorylation is not known. That cyclic AMP causes similar changes (A.M.G. and I.G.W., unpublished), and that the hepatic concentration of the cyclic nucleotide is elevated in diabetes<sup>3</sup>, suggests that it is increased phosphorylation resulting from the activation of a protein kinase that is responsible. The changes in S6 are by no means specific for diabetes: similar alterations occur during hepatic regeneration<sup>1</sup> and after administration of glucagon or cyclic AMP (A.M.G. and I.G.W., unpublished); and probably after administration of other hormones as well<sup>2,3,14</sup>. Insulin is the first agent, however, found to decrease phosphorylation of liver ribosomal protein. Insulin has also been reported to promote phosphorylation of

membrane and ribosomal protein in mammary gland stem cells<sup>15</sup>, although the phosphorylation of the ribosomes was not adequately characterised<sup>1</sup>.

The functional significance of the phosphorylation of S6 is not known, although the possibilities have been discussed<sup>1</sup>. Since the impact, if any, of the phosphorylation of S6 is not known, it is impossible to say whether the change bears a causal relation to the alterations induced by diabetes in protein synthesis<sup>16-18</sup>.

## Phosphorylation of ribosomal proteins in HeLa cells infected with vaccinia virus

MODIFICATION of ribosomal proteins has been suggested as a mechanism controlling protein biosynthesis<sup>1</sup>. *In vivo* and *in vitro* phosphorylation of eukaryotic ribosomal proteins has been described and its possible functional relevance discussed<sup>2-5</sup>. Two-dimensional polyacrylamide gel electrophoresis has shown that only one, small ribosomal subunit protein, S6, is phosphorylated in rat liver<sup>6</sup>. The number of phosphoserine residues in this protein increases by an order of magnitude during liver regeneration<sup>6</sup> and also after administration of inhibitors of protein synthesis<sup>7</sup>. In addition, when *Escherichia coli* is infected with bacteriophage T7, various host cell proteins, including some ribosomal proteins, are phosphorylated<sup>8</sup>. In our search for possible regulatory changes in the protein synthesising apparatus of virus-infected cells, we have now examined the phosphorylation of ribosomal proteins in HeLa cells infected with vaccinia virus.

Infection of HeLa cells with vaccinia virus caused a fourfold increase in the amount of radioactive phosphate incorporated into the ribosomal proteins of 40S ribosomes (Table 1). There is no difference in the specific radioactivity between 60S ribosomal proteins from uninfected and virus-infected cells. (Radioactivity in the total protein from uninfected 60S subunits cannot be due entirely to contamination of 60S subunits with 40S subunits. We are investigating whether it might be attributed to acidic phosphoproteins.) Subsequent treatment of ribosomal proteins with hot trichloroacetic acid (TCA) and organic solvents (to remove residual contamination due to RNA or phospholipids, respectively) did not substantially affect the difference in specific radioactivity between ribosomal proteins of 40S subunits from infected and uninfected cells.

The proteins of 80S ribosomes were extracted and separated by two-dimensional polyacrylamide gel electrophoresis in conditions which resolve only basic ribosomal proteins (Fig. 1).

**Table 1** Incorporation of radioactivity from <sup>32</sup>P-orthophosphoric acid into the protein of ribosomal subunits from uninfected and vaccinia virus-infected HeLa cells

Experiment	Treatment	<sup>32</sup> P radioactivity in ribosomal protein (c.p.m. µg <sup>-1</sup> )			
		Uninfected		Infected	
		40S	60S	40S	60S
a	Cold TCA	60	72	192	85
b	Hot TCA	42	45	192	69
c	Organic solvents	45	58	179	59

HeLa cells were infected with vaccinia WR virus at 1,000 virions per cell as described<sup>9</sup>. Infected and mock infected cells were suspended after virus adsorption in phosphate-free medium and labelled with <sup>32</sup>P-orthophosphate (50 µCi ml<sup>-1</sup>). After 2.5 h of incubation, cells were washed and homogenised and ribosomal particles were pelleted<sup>10</sup>. The nascent polypeptides were released by treatment with 1 mM puromycin and ribosomes were separated by sucrose gradient centrifugation<sup>10</sup> in 20 mM Tris-HCl, pH 7.5, 500 mM KCl, 3 mM MgCl<sub>2</sub>, 5 mM β-mercaptoethanol. The ribosomal proteins were extracted, dialysed and lyophilised according to the procedure of Sherton and Wool<sup>11</sup>. <sup>32</sup>P-ribosomal proteins were precipitated with (a) 10% TCA at 0 °C, the precipitate was collected after 30 min at 0 °C on glass fibre disks and washed with cold 5% TCA. b, As in a but heated for 20 min at 90 °C in 10% TCA before filtration. c, As in b except that additionally the samples on the disks were extracted with 10 ml of ethanol-ethyl ether (3:1) at 60 °C and as well as with 10 ml of ethyl ether and cold acetone.

Comparison of the stained gels revealed an additional protein located to the left (anodically) of protein S2 in ribosomes from virus-infected cells. Also, the density of staining of protein S2 from infected cells decreased. Autoradiographs of these gels show one phosphoprotein (P1) in uninfected HeLa cells and three phosphoproteins among the ribosomal proteins of virus-infected HeLa cells. Phosphoprotein P1 is common to both types of cells whereas P2 and P3 are only observed with ribosomes of infected cells. These phosphoproteins fulfil satisfactorily the criteria for ribosomal phosphoproteins<sup>13</sup>. (1) Ribosomes have been centrifuged twice through 0.5 M KCl, 0.003 M MgCl<sub>2</sub>. (2) Phosphate is bound covalently to serine and threonine (not shown). (3) The covalently bound phosphate migrates with ribosomal proteins on gels. Further, the treatment with (4) hot TCA and (5) organic solvents showed that the contamination of ribosomal proteins with RNA or phospholipids is negligible.

To estimate quantitatively the amount of phosphate incorporated into individual proteins, proteins were cut out of the gel and <sup>32</sup>P radioactivity was determined. Table 2 shows that spot P1 is labelled in both types of cells whereas regions corresponding to P2 and P3 are not detectably labelled in uninfected cells.

We have undertaken experiments to enumerate the ribosomal proteins of HeLa cells (D. Schiffmann and I. H., unpublished). According to this nomenclature of ribosomal proteins we have identified phosphoprotein P1 as S6 and P2 as S2. We assume that the additional protein spot observed in ribosomes from virus-infected cells (left of the normal position of S2) represents phosphorylated molecules of S2 protein. Its negative phosphate groups cause slower migration to the cathode in the first dimension. The lack of staining of gels in the radioactive

**Table 2** Radioactivity in individual phosphoproteins separated by two-dimensional polyacrylamide gel electrophoresis

Protein	<sup>32</sup> P radioactivity (c.p.m.) in protein from	
	uninfected cells	virus-infected cells
P1 (S6)	871	1,417
P2 (S2)	4	1,809
P3 (?)	0	544

The protein spots were cut out with a cork borer and their radioactivity was determined<sup>13</sup>. The radioactivity in the remaining ribosomal proteins (not shown) did not exceed 25 c.p.m. per spot. This blank value of 25 c.p.m. was subtracted from the values in the table.

**Fig. 1** Two-dimensional electrophoresis of  $^{32}\text{P}$ -ribosomal proteins from 80S ribosomes. Ribosomal proteins were prepared as described in the legend to Table 1. In (a) 820  $\mu\text{g}$  of protein from uninfected cells and in (b) 820  $\mu\text{g}$  of protein from virus-infected cells were separated by two-dimensional polyacrylamide gel electrophoresis<sup>12</sup>, stained with Amido black and photographed. The circles indicate the radioactive areas from the autoradiographs. c, Autoradiograph of the gel a; d, autoradiograph of the gel b. There are no further spots on the autoradiographs beyond the confines of the figure.

area of phosphoprotein P3 suggests a high degree of phosphorylation. Because a high degree of phosphorylation could significantly alter the mobility of a ribosomal protein, it is difficult to ascertain whether or not P3 is a phosphorylated ribosomal, a non-ribosomal cellular or a viral protein.

The mechanism by which ribosomal phosphoproteins arise is not known. Two different reactions, phosphorylation by a kinase and dephosphorylation by a phosphatase, have been considered in the case of protein S6 from rat liver ribosomes<sup>7</sup>. A further possibility might be the phosphorylation of ribosomal proteins by a virion-associated protein kinase, such as that described in vaccinia virions<sup>14</sup> and suggested to be involved in the regulation of host cell functions<sup>15</sup>. Finally, intracellular concentrations of cyclic AMP might be altered in infected cells and consequent effects on the phosphorylation of ribosomal proteins cannot be ruled out.

We cannot say whether the phosphorylation of ribosomal proteins is correlated with functional changes of the translational apparatus caused by the virus. It is tempting to speculate that the phosphorylation of ribosomal proteins is related to the switch off of host cell protein synthesis in virus-infected cells or to the specific selection of viral and cellular mRNAs for translation.

We thank Dr V. Erdmann and Miss A. Schreiber for help with two-dimensional gel electrophoresis, and Drs I. Dawid, V. Erdmann and E. Wecker for critical reading of the manuscript. This work was supported by the Deutsche Forschungsgemeinschaft. M. K. was supported by a predoctoral training grant from the University of Würzburg.

## Evidence that mutations in the *suA* polarity suppressing gene directly affect termination factor rho

THE *suA* mutation in *Escherichia coli* is defined by its suppression of the polar effects of nonsense mutations on distal genes<sup>1</sup>. Richardson *et al.*<sup>2</sup> discovered that two independent mutations in the *suA* gene affect the transcriptional termination factor rho. This suggests<sup>2</sup> a mechanism for polarity: as long as ribosomes progress along the nascent message, transcription proceeds; but when ribosomal progress is blocked, exposure of the distal RNA somehow causes rho to terminate transcription prematurely. As others have noted<sup>3-6</sup>, the involvement of rho in translational polarity could explain several puzzling observations concerning the control of both transcription and translation. Richardson *et al.*<sup>2</sup> proposed that rho may be the product of the *suA* gene. They hesitated to draw that conclusion, however, because they found

a rather high level of rho activity, 9% of wild type, in a strain believed<sup>7</sup> to contain an amber mutation in the *suA* gene (strain 2055). Either this amber lesion was extraordinarily leaky or, alternatively, the absence of *suA* gene function only partially and indirectly diminished the level of rho activity in the cell. The experiments reported here clarify this problem and argue that the transcriptional termination factor rho is indeed the direct protein product of the *suA* gene.

While examining the binding of bacterial and bacteriophage proteins to affinity resins which contain immobilised *E. coli* RNA polymerase<sup>8</sup>, I noticed that some preparations of immobilised polymerase retained the *E. coli* rho factor.

**Fig. 1** Comparison of the rho polypeptide of *suA* strain 2055 with that of the *su*<sup>-</sup> parent strain 2034. Radioactive cell extracts were prepared by freeze-thaw lysis, digestion of nucleic acids with DNase I and micrococcal nuclease, and brief centrifugation to remove debris (for details, see ref. 8). Extracts (25 µl, corresponding to 1 ml of original cell culture) were applied to affinity columns containing roughly 5 µg of immobilised RNA polymerase. The RNA polymerase holoenzyme used in the affinity resin had been purified through step V of the procedure of ref. 11 and then sedimented down a low salt glycerol gradient; the resulting enzyme is 90–95% pure, as judged by SDS–polyacrylamide gel electrophoresis. The preparation of the affinity resin and the microchromatographic procedures used have been described<sup>8</sup>. The figures show autoradiograms of the 1 M NaCl column elutions analysed on SDS–10% polyacrylamide slab gels<sup>8</sup>. The autoradiograms, using Kodak single-coated blue-sensitive X-ray film, were exposed for 10 d for samples *a* and *b*, and for 7 d for samples *c–e*. *a*, A culture of *su*<sup>-</sup> 2034, grown at 37°C to  $A_{550} = 0.60$  in minimal medium, was pulsed for 7 min with 100 µCi ml<sup>-1</sup> <sup>35</sup>S-methionine, chased briefly (3 min) with excess non-radioactive methionine, and collected on ice<sup>8</sup>. *b*, A parallel culture of *suA* 2055 was treated as above. *c*, A culture of 2034 was grown in minimal medium containing 4 µg ml<sup>-1</sup> <sup>35</sup>SO<sub>4</sub><sup>2-</sup> (New England Nuclear Corp.), 350 µCi ml<sup>-1</sup>. At  $A_{550} = 0.30$ , non-radioactive SO<sub>4</sub><sup>2-</sup>, methionine and cysteine were added in excess to prevent further incorporation of label; the chased cells were then grown for one further generation and collected. *d*, A parallel culture of 2055 was treated as above. *e*, Immediately before loading the affinity resin with a 25 µl sample of the 2034 extract described in *c*, the column was first saturated for rho by the addition of 3 µg of purified rho factor (given by R. Maurer, prepared by the method of Roberts<sup>12</sup>).

**Fig. 2** Analysis of the rho proteins of polarity suppressor strains isolated by M. Malamy. Procedures were as described in Fig. 1. The radioactive pulse was for 7 min, followed by a 3 min chase. Affinity columns contained 15 µg RNA polymerase, and the final autoradiogram was exposed for 2 d. *a*, RV Na1, the *su*<sup>-</sup> parent; *b*, RV Na1 *su*<sup>115</sup>; *c*, RV Na1 *su*<sup>218</sup>; *d*, RV Na1 *su*<sup>221</sup>.

Subsequent experiments have shown that the ability to bind the rho protein is not an intrinsic property of immobilised RNA polymerase, but derives from the presence of a contaminant (possibly rho itself) in some preparations of the polymerase holoenzyme. I have, nevertheless, used these affinity resins to examine the rho protein of several *E. coli* strains. Making use of a slight difference in the molecular weights of the rho polypeptides of strain K12 and B/r, I mapped the rho gene near *ilv* at 75' on the *E. coli* genome<sup>9</sup>. (The observations reported here, in conjunction with the experiments described in ref. 9, make it almost certain that I have identified the structural gene for rho, and not some strain-specific modifier of the rho protein.) Pl co-transduction experiments showed the *rho* gene to be tightly linked to the *suA* locus (see ref. 9); and I was thereby led to examine the rho protein of several polarity suppressor strains.

To observe the rho polypeptide, I prepared crude cell extracts from <sup>35</sup>S-methionine pulsed cultures using freeze-thaw lysis and mild nuclease digestion (see the legend to Fig. 1 for details); the extracts were then applied to affinity columns which were subsequently eluted with a 1 M NaCl buffer. Figure 1 shows the sodium dodecyl sulphate (SDS)–polyacrylamide gel profiles of several of these column elutions. The polarity suppressing mutant 2055, the presumed *suA* amber<sup>2,7</sup>, produces a rho polypeptide of normal molecular weight in amounts comparable with that made by the (*su*<sup>-</sup>) parent strain, 2034, during this pulse (compare columns in Fig. 1*a* and *b*). If the radioactive labelling protocol is changed, however, so that the cells are chased for one generation before collection, then the rho lesion in mutant 2055 becomes apparent: the columns in Fig. 1*c* and

*d* show that the rho protein of the parent strain is relatively stable during the *in vivo* chase, but the rho polypeptide of the polarity suppressed strain can no longer be detected after this treatment. The final column in Fig. 1e demonstrates that the autoradiographic band designated as rho represents this protein: in this experiment, previous addition of excess purified rho to the affinity resin totally and specifically overcame the binding of the radioactive rho protein in the 2034 extract.

The observation of wild-type levels of the full-sized rho polypeptide in pulsed extracts of *suA* mutant 2055 is not compatible with the assumption that 2055 harbours an amber mutation in the *rho* gene. On the contrary, the data of Fig. 1 suggest that 2055 may be a missense mutation resulting in an unstable rho protein. Genetic experiments confirmed that the *suA* phenotype of 2055 is not (currently) due to an amber mutation. Following the method which Morse and Guertin<sup>7</sup> used to detect the original amber mutation, I introduced the *su3* amber suppressor into strain 2055 (of genotype<sup>7</sup> *W3110 tryp E' ochre 9851, leu<sup>-</sup>amber 277, suA 120*) with  $\phi 80\text{psu3}$ , selecting *leu<sup>+</sup>* lysogens and then scoring for the continued expression of the *suA* allele. Each colony tested (22 independent isolates from the 2055 stab) continued to express its *suA* phenotype even in the presence of the *su3* amber suppressor. Examination of other strains presumed to carry the *suA* amber allele (2054 from D. Morse, and CU111 (a derivative of 2054) from H. Umbarger<sup>10</sup>) revealed no cells with true *suA* amber mutations. D. Morse and J. Richardson (personal communications) confirm that now the *suA* phenotype of these strains is not the result of an amber mutation in that locus. Since the *suA* lesion in strain 2055 is a missense mutation producing an unstable rho protein, the 9% level of activity detected by Richardson *et al.*<sup>2</sup> is in complete agreement with the contention that rho is the primary gene product of the *suA* locus.

I have screened the rho proteins of another set of polarity suppressed mutants, those isolated by M. Malamy (in preparation) for their effect on insertion mutations in the lactose operon<sup>13</sup>. The polarity suppressing mutations map at 75' and are presumed to lie in the locus originally designated *suA*. Figure 2 shows that three of these mutations do affect rho. In mutant 221, the rho polypeptide is of slower gel mobility (presumably greater molecular weight) than normal. The simplest interpretation of the 221 effect is that the *suA* mutation lies in the structural gene for rho. Each of the *suA* strains seems, by this method of detection, to overproduce the rho protein. Mutant 115, the strongest polarity suppressor in that collection (M. Malamy, personal communication), is the greatest overproducer. Densitometry of the autoradiograms indicates that pulsed cultures of strain 115 contain at least three times as much radioactivity in the rho polypeptide as the RV Nal parent strain. (Even after a one generation chase, strains 221 and 115 display at least as much radioactive rho as the parent strain.) It is surprising that these polarity-suppressing strains, presumed to contain diminished rho activity, seem to overproduce the rho polypeptide. This may be an indication of autoregulation of rho synthesis, conceivably the result of a rho-dependent attenuation of transcription<sup>14</sup> of the *suA* gene.

The *suA* mutations described here affect rho in disparate ways: strain 2055 makes an unstable rho; other strains, especially *su<sup>115</sup>*, overproduce rho; and *su<sup>221</sup>* apparently increases the molecular weight of the polypeptide. There are other mutations, linked to *ilv*, that affect specific termination processes. The mutants of Bertrand *et al.*<sup>14</sup>, which suppress attenuation of the tryptophan operon, also suppress polarity, but the *sun* mutants described by Brunel and Davison<sup>15</sup>, relieving the N requirement of phage  $\lambda$ , do not. The widely differing phenotypes of all these mutants are probably a consequence of the necessarily subtle nature of

mutations allowed in rho, reflecting the essential role that rho must have in bacterial transcription.

I thank D. Morse and M. Malamy for bacterial strains, J. Richardson for communicating results before publication, and W. Gilbert for advice. This research was supported by grants from the National Institutes of Health.

## Exhaustion and recovery of repair excision of *O*<sup>6</sup>-methylguanine from rat liver DNA

EVIDENCE continues to accumulate that the *O*<sup>6</sup> position of guanine in DNA is a critical reaction site for the initiation of malignant transformation by monofunctional alkylating agents. *O*<sup>6</sup>-alkylguanine has been shown to be promutagenic and the relative extent of its formation by different compounds approximately corresponds to their carcinogenic potency<sup>1-3</sup>. In contrast to 7-alkylguanine, which is the major reaction product in nucleic acids, *O*<sup>6</sup>-alkylguanine can be enzymically excised from DNA<sup>4-7</sup> and the tissue-specific carcinogenic action of alkylating carcinogens seems to depend on the differential capacity of the various organs to actively remove this base from their DNA<sup>8-11</sup>. The principal target organ in the carcinogenicity of *N*-methyl-*N*-nitrosourea (MNU) is the nervous system and it has been shown that *O*<sup>6</sup>-methylguanine (*O*<sup>6</sup>-meG) is removed much less rapidly from brain DNA than from that of any other rat tissue<sup>6,11</sup>. The liver is not susceptible to the carcinogenicity of MNU (except after partial hepatectomy<sup>12</sup>) and this organ has been found to be most efficient in the repair excision of *O*<sup>6</sup>-meG (ref. 11). We have noted<sup>9</sup>, however, that the loss of *O*<sup>6</sup>-meG from liver DNA is influenced markedly by the dose of MNU administered; higher levels of *O*<sup>6</sup>-meG are less rapidly removed. We now present evidence that the excision repair system for *O*<sup>6</sup>-meG in rat liver can be overloaded with sublethal doses of MNU and related carcinogens, and requires several days to recover and restore its initial capacity.

In all experiments, female BD-IX rats (110-140 g) received an intravenous injection of 10 mg kg<sup>-1</sup> <sup>3</sup>H-MNU and were killed 6 h later. Liver DNA was isolated and purine bases were separated by Sephadex G-10 chromatography of the acid hydrolysate<sup>11</sup>. After injection of <sup>3</sup>H-MNU alone *O*<sup>6</sup>-<sup>3</sup>H-meG present in liver DNA 6 h later amounted to 3.3 × 10<sup>-4</sup> mol % of guanine (Fig. 1). When unlabelled MNU (70 mg kg<sup>-1</sup>) was administered simultaneously with, or up to 12 h before, the injection of <sup>3</sup>H-meG the amount of *O*<sup>6</sup>-<sup>3</sup>H-meG present 6 h later was 7-10 times higher, indicating that it was excised from DNA at a considerably lower rate. The excision capacity of the liver gradually recovered during longer pretreatment intervals but even 7 d after the injection of unlabelled MNU the initial rate

**Fig. 1** Amounts of  $O^6$ - $^3H$ -meG present in liver DNA 6 h after an intravenous injection of  $10 \text{ mg kg}^{-1}$   $^3H$ -MNU. Unlabelled MNU ( $70 \text{ mg kg}^{-1}$ ) was administered either simultaneously or at various times before injection of  $^3H$ -MNU (pretreatment interval). Asterisk on ordinate indicates amount of  $O^6$ - $^3H$ -meG present when no additional unlabelled MNU was administered. DNA was isolated by phenol extraction from the pooled livers of two rats and hydrolysed in  $0.1 \text{ M HCl}$  ( $37^\circ\text{C}$ , 20 h). Purine bases were determined after chromatography on Sephadex G-10 columns ( $1 \times 90 \text{ cm}$ ) eluted with  $0.05 \text{ M}$  ammonium formate ( $\text{pH } 6.8$ ). Extent of methylation was calculated from specific radioactivity of injected  $^3H$ -MNU ( $12.5 \text{ mCi mmol}^{-1}$ ). For details see ref. 11.

of  $O^6$ - $^3H$ -meG excision was not yet fully re-established. The effect of pretreatment with various doses of unlabelled MNU on the amount of  $O^6$ - $^3H$ -meG persisting in liver DNA is shown in Fig. 2. In this experiment, a constant pretreatment interval of 3 h was chosen. The results provide no evidence for a threshold effect: even pretreatment with a dose of only  $10 \text{ mg kg}^{-1}$  MNU significantly increased the amount of  $O^6$ - $^3H$ -meG present 6 h after the administration of  $^3H$ -MNU.

To test the specificity of the pretreatment effect, sublethal doses of X rays and agents of various carcinogenic potency were applied (Table 1). Compounds known to produce a high extent of alkylation in the  $O^6$  position of guanine (ethylnitrosourea, dimethylnitrosamine<sup>3</sup>) markedly reduced the excision of  $O^6$ - $^3H$ -meG produced by the subsequent injection of  $^3H$ -MNU. Methyl methanesulphonate was given at a dose ( $85 \text{ mg kg}^{-1}$ ) known to produce approximately the same total extent of alkylation of DNA as  $70 \text{ mg kg}^{-1}$  MNU<sup>13</sup>. The effect of methyl methanesulphonate pretreatment on the excision of  $O^6$ - $^3H$ -meG, however, was equivalent to a dose of only about  $4 \text{ mg kg}^{-1}$  MNU (Table 1, Fig. 2). This could be explained by the fact that  $4 \text{ mg kg}^{-1}$  MNU would be expected to produce approximately the same amount of  $O^6$ -meG as  $85 \text{ mg kg}^{-1}$  methyl methanesulphonate<sup>3,14</sup>. At the same time, the results of methyl methanesulphonate

administration indicate that the pretreatment effect on  $O^6$ -meG excision is indeed mediated by the production of  $O^6$ -alkylguanine itself rather than alkylation products such as 7-alkylguanine. The other agents used for pretreatment (Table 1) are not known to produce  $O^6$ -alkylation of guanine. The small effects observed after pretreatment with *N*-nitrosomorpholine, 7,12-dimethylbenz [*a*] anthracene and cyclophosphamide suggest that these agents may only to a limited extent produce DNA lesions which are recognised and repaired by the  $O^6$ -meG excision system. Ethionine, like nitrosomorpholine a potent liver carcinogen, reacts with DNA to only a very small extent<sup>15</sup> and was found to have no effect on the excision of  $O^6$ - $^3H$ -meG from liver DNA. X irradiation was the only pretreatment which caused a more rapid excision, although to only a small extent.

**Fig. 2** Effect of various pretreatment doses of MNU on excision of  $O^6$ - $^3H$ -meG from rat liver DNA *in vivo*. Animals received  $10$ – $70 \text{ mg kg}^{-1}$  unlabelled MNU. After an interval of 3 h, they were given  $^3H$ -MNU ( $10 \text{ mg kg}^{-1}$ ) and killed 6 h later. For experimental details, see Fig. 1.

The results obtained cannot be explained by an increase in the overall rate of alkylation attributable to the pretreatment since this would proportionally lead to an increase in alkylation at the 7 position of guanine. Only minor changes in the  $7$ - $^3H$ -meG levels, however, were found: the decrease in the  $O^6$ -meG excision was evident from an increase in both the absolute amounts of  $O^6$ - $^3H$ -meG and the  $O^6$ -/ $7$ - $^3H$ -meG ratio (Table 1).

The present study shows that rat liver may efficiently excise  $O^6$ -alkylguanine produced by a single dose of an alkylating carcinogen but that a second dose, given after an interval of less than about 12 h, produces additional DNA damage which is much less efficiently repaired. This may correspond to the observation that liver carcinogens in general do not produce tumours when given as a single

**Table 1** Effect of pretreatment with various agents on excision of MNU-induced  $O^6$ -meG from rat liver DNA

Pretreatment	Dose	Route	$O^6$ - $^3H$ -meG*	Ratio $O^6$ -/ $7$ - $^3H$ -meG
Control	—	—	3.3	0.018
X irradiation†	400 R	—	1.8	0.011
DL-Ethionine	$750 \text{ mg kg}^{-1}$	i.p.	3.2	0.023

## Altered C-terminal salt bridges in haemoglobin York cause high oxygen affinity

STUDIES of abnormal human haemoglobins (Hbs) with increased  $O_2$  affinity have been particularly useful in developing detailed molecular interpretations of normal Hb function. A number of functionally interesting mutants are altered in the  $\beta$ HC region but only one variant, Hb Hiroshima ( $\beta$ 146 His $\rightarrow$ Asp)<sup>1,2</sup>, has been reported as having a substitution at the C terminus itself. We report here the structure and  $O_2$  equilibria of Hb York, a new mutation at the  $\beta$ 146 position, His $\rightarrow$ Pro, associated with increased  $O_2$  affinity, decreased cooperativity and diminished Bohr effect.

Hb York was discovered during investigation of mild asymptomatic erythrocytosis in a 22-yr-old Caucasian woman. Preliminary measurements showed markedly increased whole blood  $O_2$  affinity, suggesting the presence of an abnormal Hb. Although Hb electrophoresis on starch gel or on cellulose acetate at alkaline pH failed to reveal an abnormal band, two major components were separated on agar gel electrophoresis at pH 6.0 in 0.05 M citrate buffer<sup>3</sup>. Hb York migrated more rapidly towards the cathode than Hb A and constituted approximately 50% of total Hb.

Hb York was separated from Hb A on carboxymethyl-cellulose<sup>3</sup>, and was shown to be homogeneous on agar gel electrophoresis. The presence of approximately equal amounts of Hb A and York suggested that Hb York was a  $\beta$  mutant. The fractions containing Hb York in the CO form were concentrated by pressure ultrafiltration and dialysed exhaustively against 0.1 M NaCl.

Purified Hb York was converted to globin with cold acid acetone<sup>4</sup>. The abnormal  $\beta$  chain was isolated by the method of Clegg *et al.*<sup>5</sup>. Amino acid analysis of the HCl-hydrolysed  $\beta$  chain showed a low value for histidine and a high value for proline compared with  $\beta^A$  chains. The  $\beta^{\text{York}}$  chains were aminoethylated as described previously<sup>6</sup> and digested with trypsin<sup>7</sup>. The tryptic peptides were chromatographed on Aminex A-5 (ref. 8), and the chromatogram appeared similar to that resulting from a tryptic digest of  $\beta^A$  chains except that the  $\beta$ T-15 (Tyr–His) was absent. Rechromatography on Aminex AG 50W-X4 of a fraction containing the  $\beta$ T-4 and an abnormal peptide gave a good yield of a peptide having the amino acid

composition shown in Table 1. This corresponds to the normal  $\beta$ T-14,15 peptide except that a histidine has been replaced by proline. This substitution was confirmed by analysis of the peptides resulting from partial hydrolysis of the  $\beta$ T-14, 15 peptide by thermolysin (Calbiochem, Crystalline B Grade)<sup>9</sup>. Analysis of the other tryptic peptides following HCl hydrolysis revealed them to have normal composition.

To distinguish between mutation of the  $\beta$ 146 and  $\beta$ 143 histidine residues, tryptic hydrolysis of the  $\beta$  chain after glycinamidation by the method of Carraway and Koshland<sup>10</sup> was carried out. A normal  $\beta$ T-14 peptide was obtained in good yield, indicating that the mutation was at the  $\beta$ 146 rather than the  $\beta$ 143 histidine. The glycinamidated  $\beta$ T-15 (Tyr–Pro) peptide was not observed, presumably owing to the degrading effect of glycinamidation on tyrosine residues.

Carboxypeptidase A digestion of  $\beta^A$  and of  $\beta^{\text{York}}$  chains was carried out according to Ambler<sup>11</sup> in 2 M urea at pH 8.5 for 2 h at 37 °C. Although both Tyr and His were removed from the  $\beta^A$  chain, no amino acid residues were removed from  $\beta^{\text{York}}$ . Proline at the C terminus would be expected to resist the enzyme. Hb York is therefore  $\beta$ 146 (His $\rightarrow$ Pro).

Functional studies of Hb York revealed a very high  $O_2$  affinity and diminished Bohr effect and cooperativity. The  $\log P_{50O_2}$  of Hb York was 0.04 in contrast to 0.71 for similarly prepared Hb A, measured at 20 °C in 0.1M phosphate, pH 7.0. The alkaline Bohr effect of Hb York was approximately 50% normal ( $\Delta \log P_{50}/\Delta pH = -0.36$  compared with  $-0.65$  for Hb A). Hill's '*n*' for Hb York is 1.8 ( $\pm 0.2$ ) compared with 2.5 for Hb A in these conditions, and did not change with pH. The effect of the organic phosphates, 2,3 diphosphoglycerate (DPG) and inositol hexaphosphate (IHP), on the  $O_2$  equilibria of Hb York and Hb A is shown in Table 2. DPG and IHP are known to bind to the  $\beta$  chains and stabilise the quaternary conformation of deoxy Hb, thus lowering  $O_2$  affinity. The changes of  $\log P_{50O_2}$  of Hb York produced by DPG and by IHP are similar to those observed with Hb A. In contrast to the diminution of Hill's '*n*' to 1.6 observed with Hb A in the presence of IHP, the value for Hb York was increased from 1.8 to 2.2. The visible and ultraviolet spectra of Hb York were similar to those of Hb A.

Hb York may be contrasted with Hb Hiroshima ( $\beta$ 146, His $\rightarrow$ Asp)<sup>2</sup>. Both mutants have a similarly reduced Bohr effect owing to loss of the intrachain salt bridge between the  $\beta$ 146 histidyl imino  $NH^+$  and the  $\beta$ 94 aspartyl carboxylate group. The Bohr effect of des-(His- $\beta$ 146) Hb A has also been shown to be diminished<sup>13</sup>. The  $O_2$  affinity of Hb York is,

**Fig. 1** Model of C-terminal region of  $\beta$  chain of deoxy Hb York showing proposed salt bridge between  $\beta$ 146 Pro carboxylate and  $\epsilon$ -amino group of  $\beta$ 144 lysine. Constructed from coordinates of horse deoxy Hb except for the inclusion of prolyl residue and rotation of lysine side chain.

**Table 1** Composition of C-terminal peptides of  $\beta$  chain of Hb York (amino acid residues per haem)

Amino acid	Tryptic $\beta$ T-14,15	Thermolysin peptide from $\beta$ T-14,15	Glycinamidated tryptic $\beta$ T-14

Tyrosine	0.8(1)	1.0(1)	—(0)
Histidine	1.0(2)	0.9(2)	1.0(1)
Lysine	1.1(1)	1.1(1)	1.1(1)
Alanine	4.0(4)	1.0(1)	3.7(4)
Leucine	1.1(1)	1.0(1)	1.0(1)
Aspartic acid	1.1(1)	—	1.1(1)
Valine	3.0(3)	—	2.9(3)
Glycine	1.0(1)	—	1.0(1)

\* Values in parentheses are those expected for corresponding peptides in normal Hb.

however, significantly higher than that of Hb Hiroshima or of des-(His- $\beta$ 146) Hb A (Table 3). Hill's ' $n$ ' is lower than that observed for either of these Hbs.

The mechanism for the abnormal  $O_2$  affinity of Hb York may involve destabilisation of its 'T' conformation. This destabilisation might be due to loss not only of the intrachain salt bridge between the  $\beta$ 146 His  $NH^+$  and the  $\beta$ 94 Asp carboxylate but also to impaired formation of the interchain salt bridges between the  $\beta$ 146 carboxylate and  $\alpha$ 40 Lys  $\epsilon$ -amino group which is characteristic of the normal T conformation of deoxy Hb<sup>14</sup>. Hb Hiroshima does not lose the latter salt bridge<sup>2</sup>. We constructed a model of the C-terminal region of the  $\beta$  chain of horse deoxy Hb, using energy refined coordinates supplied by M. F. Perutz. This model indicated that formation of the

salt bridges which contribute to the stabilisation of the deoxy conformation of Hb A.

Crystals of deoxy des-(His- $\beta$ 146) Hb A have also been described<sup>15</sup> as lacking the four  $\beta$ -chain salt bridges, yet the functional properties of this haemoglobin are more similar to those of Hb Hiroshima than Hb York. The modifications to the T  $\rightleftharpoons$  R equilibrium of the des-(His- $\beta$ 146) derivative seem to be more complex<sup>16</sup> than in Hb York.

The loss of the four  $\beta$ -chain C-terminal salt bridges is not sufficient to prevent deoxy Hb York from entering the T conformation because it possesses a significant degree of cooperativity, because the effects of DPG and IHP on its  $O_2$  affinity are similar to those for Hb A, and because the visible and ultraviolet spectra of deoxy Hb York are very similar to those of deoxy Hb A. The degree of destabilisation of the T conformation proposed for Hb York, however, would be greater than that occurring in Hb Hiroshima due to the loss of the interchain salt bridges. This additional destabilisation would account for the more pronounced abnormalities of  $O_2$  binding of Hb York.

We thank R. Ladner, A. D. McLaughlin and M. F. Perutz for the energy refined coordinates of horse deoxy Hb, and Missoon Mah and Marie Duerst for assistance. Supported by the American Heart Association and the US Public Health Service.

\*  $O_2$  equilibria determined at pH 7.0 and 20 °C using a modified<sup>3</sup> technique of Benesch *et al.*<sup>12</sup>. Samples were buffered with 0.05 M bis-Tris and contained 0.1 M chloride. Formation of methaemoglobin during these experiments did not exceed 5% of the total.

$^\dagger \Delta \log P_{50O_2} = \log P_{50O_2} - \log P_{50O_2}$  (Stripped Hb).

$^\ddagger$  Hb A was prepared by passing a haemolysate from normal human adult red cells through Sephadex G-25 equilibrated with 0.1 M NaCl.

$\beta$ 146- $\alpha$ 40 salt bridge is seriously hindered in Hb York. The referee has kindly stated that "The reason why the salt bridge between the  $\alpha$ -carboxyl of Pro- $\beta$ 146 and Lys- $\alpha$ 40 is not formed is that the Pro is too close to the Cys- $\beta$ 93." The  $\beta$ 146 proline residue and the side chain of the  $\beta$ 144 lysine can, however, be readily oriented (Fig. 1) so that an intrachain salt bridge is formed between the  $\beta$ 146 carboxylate and the  $\epsilon$ -amino group of  $\beta$ 144 lysine. Formation of this salt bridge does not alter the position of the critical  $\beta$ 145 tyrosine. We suggest that this salt bridge would not be broken by transition to the 'R' conformation on oxygenation and, therefore, would not contribute to the free energy of interaction. We thus propose that the deoxy conformation of Hb York lacks the four  $\beta$ -chain C-terminal

# matters arising

## Weak interactions in the big bang

THE apparent arbitrariness of the numerical values assumed by the various constants of physical theory has from time to time led to the conjecture that these quantities may not be fixed numbers at all, but vary from epoch to epoch as the Universe evolves. Such a suggestion was advanced, on the basis of some discussion about gauge theories and spontaneous symmetry breaking, by Domokos, Janson and Kövesi-Domokos<sup>1</sup> in connection with the weak interaction coupling strength. They propose that this coupling strength was comparable with electromagnetism during the primordial fireball phase of the big bang (specifically, before  $T \approx 10^5$  K). This is some  $10^{10}$  times greater than at present, and its consequences are being investigated by the authors.

One consequence which they will discover is that, on general grounds, the lifetime of the neutron against  $\beta$  decay,  $n \rightarrow p + e^- + \bar{\nu}$ , would presumably be reduced by the same factor of  $\sim 10^{10}$ , making the half life of neutrons in the fireball phase a mere  $10^{-7}$  s or so. The implications of this are profound. According to current models of the hot big bang, protons and neutrons are maintained in thermodynamic equilibrium by electron-positron processes until the end of the lepton era at  $\sim 1$  s ( $10^{10}$  K). After this, the electron-positron pairs annihilate, and the neutron/proton abundance ratio is thereafter 'frozen in' until the temperature drops sufficiently low (about  $10^9$  K) for helium synthesis to occur. Essentially all the remaining neutrons are incorporated into helium (where they remain stable) after a few hundred seconds, which is well within the currently measured lifetime of the neutron.

Accepting the model of Domokos *et al.* would lead to the conclusion that the neutron abundance would not remain frozen at all during the intermediate cooling phase, but would decay to virtually zero long before nucleosynthesis could begin. The consequences of that would be an absence of neutrons in the universe—indeed, a universe composed entirely of hydrogen!

Strand, London WC2, UK

DOMOKOS ET AL. REPLY—DAVIES' remark<sup>1</sup> concerning our recent letter<sup>2</sup> raises a relevant issue; in fact, we have been studying this problem for some time. If interpreted literally, our result may lead to the paradox pointed out by Davies. The careful reader will, however, have noticed that in order to illustrate the basic idea expressed in our letter (generation of a distinction between weak and e.m. interactions through a cosmological background) we took an extremely crude idealisation of an expanding universe. In fact, our input scalar curvature is:  $R/(3p - \rho) = 0$  ( $x < x_0$ ) and  $R \sim x^{-3}$  ( $x > x_0$ ). In such a universe the temperature drops abruptly from infinity to essentially 'zero' at  $x_0$ . Hence, for  $x < x_0$  there is no nucleus formation and no neutron decay either (due to an infinite time dilatation factor). All this can take place only for  $x > x_0$ . Then  $\phi(x)$  rises very rapidly and gets close to its present value quite soon. Thus, even in this highly idealised model, there seems to be no qualitative contradiction with usual ideas of He formation. On the basis of computer experiments performed with more realistic models, we are now under the impression that the general shape of the curve  $\phi(x)$  is correctly given by our model<sup>2</sup>. Davies' observation imposes a consistency condition on more realistic model calculations:  $\phi$  must come out to be substantially different from zero during the epoch of primordial He formation.

We thank P. C. W. Davies for informing us about his observations before publication. This research is being supported by the US Energy Research and Development Administration.

## Methylation of organolead and lead(II) compounds to $(CH_3)_4Pb$ by microorganisms

RECENTLY evidence<sup>1</sup> showed that microorganisms can transform certain lead compounds into  $Me_4Pb$ ; addition of  $Me_3PbOAc$  to sediment samples apparently always increased the production of  $Me_4Pb$ . The addition, of lead(II) compounds did not, however, lead to definite effects, and with pure bacterial isolates no transformation of  $Pb^{2+}$  to  $Me_4Pb$  could be observed<sup>1</sup>. Doubt has since been cast<sup>2</sup> on the significance of a microbiological conversion of  $Me_3PbOAc$  to  $Me_4Pb$ , preferring a chemical mechanism;

also alkylation of  $Pb(NO_3)_2$  could not be detected (ref. 2).

Our studies of the behaviour of lead compounds in the presence of microorganisms show that  $Pb^{2+}$  can be biologically alkylated to  $Me_4Pb$ , and this helps to explain the formation of  $Me_4Pb$  from  $Me_3PbOAc$  in anaerobic systems.

In aqueous solution, alkyl lead compounds  $R_2PbX_2$  and  $R_3PbX$  ( $X = \text{anion}$ ) redistribute according to

reaction (2) is much faster than (1)<sup>3,4</sup> and therefore  $Me_3PbX$  seems to be relatively stable at room temperature. The stoichiometry of its decomposition can be described practically by reaction (3).

In water samples (dilution water<sup>5,6</sup>) seeded with microorganisms from an aerated aquarium, we observed, apart from the inhibition of biodegradation, that di-alkyl and tri-alkyl lead concentrations decreased considerably faster in both aerobic and anaerobic conditions than in sterile samples, and that the proportions of products no longer agrees with predictions from the above system of equations. After addition of  $Me_3PbCl$  to an anaerobic sample, less  $Pb^{2+}$ , but more  $Me_4Pb$  was formed than is required by reaction (3). Furthermore, the amount of  $Me_4Pb$  produced in a given time was considerably higher than from a sterile sample (by a factor of 5–10 in a week). Therefore the possibility that  $Me_4Pb$  was produced only by redistribution (reaction (1)), could be excluded, and it was an obvious assumption that  $Me_3PbCl$  and/or  $Pb^{2+}$ , formed according to reaction (3), had been alkylated by microorganisms to  $Me_4Pb$ .

We then investigated whether  $Pb^{2+}$  could be alkylated by microorganisms in the same anaerobic conditions. We inoculated water samples containing  $Pb(OAc)_2$  in different low concentrations (Table 1) and sealed the flasks after flushing with  $N_2$ . The analysis for  $Me_4Pb$  (the only volatile lead compound in the system) was carried out by slowly sweeping the gas phase above the solution with  $N_2$  through an 0.2 N methanolic iodine scrubber solution<sup>7</sup>; the lead content was determined colorimetrically with 4-(2-pyridylazo)-resorcinol<sup>8</sup>. The experiments were reproducible, provided that the seed was not more than 6–7 weeks old.

We therefore conclude, that besides the formation of  $Me_4Pb$  by redistribution according to reaction (1), biological alkylation of  $Pb^{2+}$  must be considered as

†Seeds were prepared from 10 ml A-water (= water from an aerated aquarium), 200 mg glucose and 10 mg urea, made up with water to 100 ml, and then incubated under N<sub>2</sub>. Seed type I: 10 ml seed (incubated for 2 weeks) + 10 ml seed (incubated for 6 weeks) + 10 ml A-water. II: 10 ml seed (incubated for 5 d) + 10 ml A-water.

‡Volatile Pb found in scrubber solution (see text).

§Amount of Me<sub>4</sub>Pb equivalent to analysed amount of Pb.

|| Same solution, additional incubation time in N<sub>2</sub>, after exchange of gas atmosphere, giving additional quantities of reaction product.

another source for Me<sub>4</sub>Pb in the experiments with Me<sub>3</sub>PbOAc (refs 1, 2). (The possibility of direct methylation of Me<sub>3</sub>PbOAc still has to be investigated.) Furthermore one can expect that the portion of Me<sub>4</sub>Pb chemically formed by redistribution is higher in sulphide systems<sup>2</sup>, as the redistribution rate greatly increases with increasing concentration of added salt MX and with increasing polarisability of X<sup>3,4</sup>. Also, since Pb<sup>2+</sup> formed according to reactions (2) or (3) is precipitated as PbS, not enough Pb<sup>2+</sup> is in solution to allow appreciable microbial alkylation to Me<sub>4</sub>Pb.

## Muscle regeneration in dystrophic mice

In their letter<sup>1</sup>, Hamburgh *et al.* set out to show that other workers in their field<sup>2</sup> had drawn incorrect conclusions from scanty experimental evidence. There are, however, certain inaccuracies in their text which do not do anything towards their claim of clarification.

In one paragraph we read that, “foetal cord from 15-d-old mouse embryos . . . were explanted”. A little later we read, “spinal cords were dis-

sected from foetal mice aged 13–14 d *in utero*”. This may seem a trivial point, but the foetal age is critical in these experiments, and such factual mistakes could lead other workers seriously astray.

Their most serious error is in the confusion of the two allelic mutant genes *dy*<sup>2</sup>*J* and *dy*. Their experiments were carried out with the *dy*<sup>2</sup>*J* mutant exclusively. They state, however, that, “normal muscle coupled with either normal or *dy* foetal spinal cord regenerated in culture”. One can only assume that these authors were using ‘*dy*’ as an abbreviation for dystrophic, or else they are guilty of negligence. Whichever applies, it seriously detracts from the value of the work.

They have also misinterpreted my letter<sup>3</sup> in which I did not confirm their work because my experimental system was entirely different. I did not say that “dystrophic” muscle would regenerate normally, since of the two mutants I described, only one (*dy*<sup>2</sup>*J*) showed regeneration which was normal. It is obvious that little attention was paid to my concluding paragraph, which emphasised the need for caution and accuracy when working with murine muscular dystrophy.

With an air of finality the authors, to whom these criticisms are directed, concede that tissue culture may no longer be a fruitful research tool in this field.

ROGER PARSONS

Muscular Dystrophy Group Research  
Laboratories,  
Regional Neurological Centre,  
Newcastle General Hospital,  
Westgate Road,  
Newcastle upon Tyne NE4 6BE, UK

<sup>1</sup> Hamburgh, M., Peterson, E., Bornstein, M. B., and Kirk, C., *Nature*, **256**, 219–220 (1975).

<sup>2</sup> Gallup, B., and Dubowitz, V., *Nature*, **243**, 287–289 (1973).

<sup>3</sup> Parsons, R., *Nature*, **251**, 621–622 (1974).

HAMBURGH *ET AL.* REPLY—We admit that the reference to foetal age may have been misleading! Timing of foetal age depends on the method of counting: some investigators call fertilisation, as shown by the appearance of the vaginal plug, day 0 whereas others call it day 1. It is always implied that any designation of foetal age is  $\pm 12$  h.

The designation ‘*dy*’ is an acceptable abbreviation for dystrophic and as the text clearly states that “phenotypically dystrophic mice were obtained from matings between tested homozygotes for the dystrophic gene *dy*<sup>2</sup>*J*”, this should have been sufficient to clarify the point.

As for Parsons’ letter<sup>2</sup> confirming our earlier work, he himself states<sup>2</sup> that “my results are essentially similar to those of Paul and of Hamburgh *et al.*”. Although there may be a difference between “results that are essentially similar” and results that confirm, it is, however, so fine, that we admit, it escaped us. Parsons states<sup>4</sup> that little attention was paid to his concluding paragraph<sup>2</sup> which emphasised the need for caution and accuracy when working with murine muscular dystrophy. We are fully familiar with the differential regenerative capacity exhibited by minced muscle obtained from the 129/ReJdy strains and the C57BL/6J *dy*<sup>2</sup>*J* strains in his culture conditions.

Our comment that the tissue culture set up may not be as well suited as originally anticipated merely expresses an experience shared by other investigators that many genetic defects do not express themselves *in vitro*. Parsons, interprets the sense of this comment to mean that “tissue culture may no longer be a fruitful research tool in this field”.

We should like to take this opportunity to mention, however, that whatever the reasons for the different result, between the experiments by Gallup and Dubowitz<sup>2</sup> and our own<sup>1</sup>, they may well be related to differential expressivity of the *dy*<sup>2</sup>*J* gene. Slightly different tissue culture environments, differences in foetal age, sex and other, yet to be identified factors, come to mind. Genes differ both in expressivity and penetrance in different environments, and gene mutations can often be revealed only by proper challenges. We consider Gallup and Dubowitz’s series to be valid and most stimulating experiments.

## Model ages

HUTCHISON *et al.*<sup>1</sup> have reported U–Pb analyses on samples of the meteorite Nakhla which confirm that this meteorite is younger than 3.68 Gyr. In both their title and their discussion there seems to be some apprehension about the ‘validity’ of model ages. Because of the considerable utility of the concept of model ages, we attempt here to clarify this matter.

Consider the number of atoms of a daughter nuclide ( $D$ ) and of its radioactive parent ( $P$ ) which are present in a sample today. Let us assume that a non-radiogenic isotope of the daughter nuclide is also present in the sample (the number of atoms being  $S$ ). For a given reference ratio  $(D/S)_M$ , the model age ( $\tau_M$ ) of the sample is given by:

$$(D/S) = (D/S)_M + (P/S)(\exp(\lambda\tau_M) - 1)$$

$\tau_M$  is the time taken for the  $(D/S)$  ratio of the sample to evolve from the reference to the measured value if the system has remained closed. The trajectory in Fig. 1 leading to the present ratio (point A) must satisfy  $D(\tau)/S(\tau) = (D/S) - (P/S)(\exp\lambda\tau) - 1$ . Point B (where the real trajectory departs from the equation) represents the last time the system was

Fig. 1 Schematic diagram showing the evolution of  $D(\tau)/S(\tau)$  with time for an open system. The value  $\tau_0$  yields the maximum age of the sample.

disturbed. The time when the system last passed through  $(D/S)_M$  is at point Q. Estimates of the initial  $(D/S)_M$  for Sr and Pb have been obtained from measurements in ancient samples with low values of  $P/S$  (refs 3–9). Designating these reference values as ‘0’ we have the corresponding model ages  $\tau_0$  given by  $(D/S) = (D/S)_0 + (P/S)(\exp(\lambda\tau_0) - 1)$ . If  $(D/S)_0$  were the lowest possible ratio for solar system material, then the corresponding model age would be a strict upper limit to its age ( $\tau_0 \geq \tau_B$ ) since  $(D/S) - (D/S)_0$  is the largest change for a closed system which is now at  $(D/S)$ . For objects which have remained closed systems since the time of the hypothetical earliest planetary objects,  $\tau_0$  would be the ‘age of the Solar System’. It follows that samples which yield model ages  $\tau_0$  in the neighbourhood

of 4.6 Gyr may represent ancient materials with a relatively simple history. Values of  $\tau_0$  which are much greater or much less than  $\sim 4.6$  Gyr constitute unequivocal evidence of open system behaviour at times less than 4.6 Gyr ago.

In general, the model age  $\tau_0$  must always be greater than the most recent time that chemical differentiation took place. For example, a devitrified glass from Nakhla yields a model age relative to ALL or BABI of  $\tau_{ALL} \approx \tau_{BABI} = 1.78$  Gyr (ref. 2). It is thus evident that Nakhla has been subject to open system behaviour for Rb and Sr, at least on a microscopic scale, more recently than  $\sim 1.78$  Gyr ago. The actual time of the last recrystallisation event was determined by a Rb–Sr internal isochron which gives an age of  $\sim 1.37$  Gyr (ref. 2). In addition to the age of crystallisation or recrystallisation of Nakhla, we can inquire whether this event consisted of local element migration (for example) on a mm scale, of an  $\sim 4.6$  Gyr-old object, or whether Nakhla formed by element mobilisation on a much coarser scale at times much younger than 4.6 Gyr. The Rb–Sr model ages for ‘total’ chips of Nakhla obtained from different meteorite fragments yield  $\tau_{BABI}$  from 3.58–2.97 Gyr, and show that the ‘total’ meteorite was produced by differentiation at times strictly younger than 3.58 Gyr. The model age arguments given above are of course applicable to all parent–daughter systems. The data of Hutchison *et al.*<sup>1</sup> show that ‘total’ rock U–Pb model ages range from 4.10–3.68 Gyr, thus requiring a differentiation time younger than 3.68 Gyr. It is evident that all these data confirm a young differentiation age for the Nakhla parent body.

Based on petrographic features, it is most plausible to consider Nakhla as an igneous rock with a simple history. The Rb–Sr data prove that this object was subject to almost complete isotopic equilibrium 1.37 Gyr ago, and analyses of ‘total’ rocks show that the parent body was differentiated at least once at a time less than 3.6 Gyr ago. While the data define a rather good linear array, however, the precise age of crystallisation or recrystallisation is not exactly defined. The ‘total’ rocks do not lie on the isochron. Since it is reasonable to assume that the total rocks are comprised of their constituent mineral phases, it follows that some mineral phases in the rock must deviate even more widely from the linear array. The small but distinct deviations of the data from an isochron seem to require that the original differentiation which produced Nakhla occurred more than 1.37 Gyr ago, or that the deviations are the result of recent alterations or analytical difficulties.

In the preceding comments we have assumed that the initial values  $(D/S)_0$  were well defined. This has been considered doubtful by Hutchison *et al.*<sup>1</sup>. For the case of Sr, an extensive search for

primitive  $^{87}\text{Sr}/^{86}\text{Sr}$  has been carried out on meteorites and lunar and terrestrial samples<sup>3,4,9,10</sup>. Since the Rb/Sr ratio in the solar nebula is  $\sim 0.5$ , the rate of evolution of  $^{87}\text{Sr}/^{86}\text{Sr}$  corresponds to a change of 0.3% per 100 Myr. It is thus possible that a wide range in initial  $^{87}\text{Sr}/^{86}\text{Sr}$  could be found in ancient Solar System objects if condensation and fractionation processes occurred for a time interval of  $\sim 10^8$  yr. The lowest  $^{87}\text{Sr}/^{86}\text{Sr}$  value so far observed is, however, below BABI by only three parts in  $10^4$  which will not significantly alter the model ages for Nakhla. With regard to the U–Pb system, the basic data as first reported by Patterson *et al.*<sup>5</sup> have been modified over the years but the essential results are not changed<sup>6–8</sup>. If we consider  $^{238}\text{U}/^{204}\text{Pb} \sim 0.3$  in carbonaceous meteorites<sup>7,8,11–13</sup> as representative of the solar nebula, then we calculate a change in  $^{207}\text{Pb}/^{204}\text{Pb}$  at 4.6 Gyr of 0.2% per 100 Myr. This rate is similar to that for  $^{87}\text{Sr}/^{86}\text{Sr}$ ; however, in contrast to the case of Sr, the rate of evolution of Pb in the solar nebula is much less than that on the Earth, Moon and many meteorites, reflecting strong U/Pb enrichment for terrestrial-type planets in the early Solar System. It is possible that the iron meteorites studied for initial Pb were produced by planetary differentiation of a body with high  $^{238}\text{U}/^{204}\text{Pb}$  and could reflect rapidly evolving Pb compositions. The general agreement of troilite Pb with that found in carbonaceous chondrites, which are certainly not planetary differentiates, would, however, seem to exclude the possibility of the large shifts in the value of primordial Pb referred to by Hutchinson *et al.*<sup>1</sup>.

We conclude that model ages provide an upper limit to the age of any system and that total rock model ages provide an insight into the differentiation processes active in planetary evolution. For Nakhla, we conclude that all methods confirm a young formation age for this meteorite, that some complexities are manifest in the detailed history of this object and finally, that no information about primitive initial isotopic compositions can be deduced from data on this young body.

This work was supported by a grant from NSF.

HUTCHISON, GALE, AND ARDEN REPLY—  
 We are grateful to Wasserburg and Papanastassiou for their courteous and clear discussion<sup>1</sup> of model 'ages' arising from our paper<sup>2</sup> on some preliminary U-Pb data for the achondritic meteorite Nakhla.

We agree that a single-stage model 'age' computed from a primitive Solar System daughter/stable nuclide ratio ( $D/S$ )<sub>0</sub> defines the oldest limit for the most recent time at which the particular system became closed. This is stated in our paper on the Rb-Sr chronology of Nakhla<sup>3</sup>. We agree also that it is likely that model 'ages' greatly different from 4.6 Gyr constitute evidence for multiple stage open system evolution. This has already been stated by one of us<sup>4</sup>. We feel, however, that it is possible that the ordinarily accepted 'primitive' Solar System initial isotopic compositions might not apply to all objects in the Solar System. In our U-Pb studies we have had several indications that they are not universally applicable. Recently discovered anomalous ratios of two light elements<sup>7</sup> suggest that we may still have something to learn about isotopic abundances in the early Solar System.

It is still our view that model 'ages' should not be used without a clear statement of their meaning, as they are readily confused with true ages by those who are unfamiliar with the field of geochronology. Further, when only a limited number of model ages are available, the upper limit set may be so far from the true age as to be misleading. An example is provided by our own Rb-Sr work on Nakhla<sup>3</sup>, where 15 Rb-Sr determinations on diopside, plagioclase, olivine and various magnetically separated mixtures, yield  $\tau_{\text{BAB}}$  model ages ranging from 5.9 to 2.33 Gyr, whereas the internal isochron yields a true age of 1.24 Gyr.

Our data indicate that the Nakhla meteorite crystallised from a melt precisely  $1.24 \pm 0.01$  Gyr ago<sup>3</sup> (not 1.37 Gyr ago<sup>8</sup>) with complete isotopic mixing. Because the U-Pb data demand a history of three (or more) stages (unless unusually low initial Pb isotope ratios are invoked) it is almost certain that a large scale chemical fractionation occurred at that time. This age is, of course, less than the whole meteorite model 'ages'. We reiterate that such a fractionation would have obliterated evidence of the earlier history

of the parent body of Nakhla. 'Gross differentiation' of the parent body (ref. 5, abstract) could, therefore, have occurred before 3.6 Gyr, if one assumes that the later, 1.24-Gyr, event was due to volcanism or impact melting on a less than planetary scale, as is discussed in more detail in ref. 3. Wasserburg and Papanastassiou<sup>1</sup> correctly argue that Rb-Sr and U-Pb model 'ages' for "total" meteorite chips require a differentiation age for the total meteorite strictly younger than 3.58 or 3.68 Gyr respectively (in fact this time is 1.24 Gyr), but incorrectly assume that this argument may certainly be extended to the parent body of Nakhla as a whole.

The presence in Nakhla of water-bearing silicate has now been confirmed, but in addition, evidence of mild, post-crystallisation shock was found<sup>6</sup>. Presumably it was during this mild shock event that the Rb-Sr system was disturbed on a millimetre scale, as shown by the failure of meteorite chip data to lie on the mineral isochron. There is no longer a need to invoke either redistribution of Rb during or after atmospheric flight<sup>3</sup>, or incomplete homogenisation of Sr 1.37 Gyr ago during dry metamorphism<sup>5</sup>. We are pleased that Wasserburg and Papanastassiou now prefer to agree with us in interpreting Nakhla as an "igneous rock with a simple history".

## North Sea phytoplankton

REID<sup>1</sup> described large scale changes in North Sea phytoplankton communities which have been detected since the mid-1960s by the Continuous Plankton Recorder survey. These changes were characterised by a marked decline in diatom populations, a possible increase in microflagellate abundance, and a decline in the zooplankton biomass. Reid concluded that eutrophication of North Sea waters and climatic changes could not, by themselves, easily explain these alterations in plankton communities.

I suggest that another set of factors, namely the presence of persistent industrial pollutants in the North Sea<sup>2</sup>,

may partially account for these changes. Many species of marine phytoplankton, particularly diatom species, show sensitivity to low levels of industrial waste products, including heavy metals<sup>3</sup>, petroleum hydrocarbons<sup>4</sup>, and stable chlorinated hydrocarbons<sup>5</sup> such as polychlorinated biphenyls<sup>6</sup>. Alterations in the species composition of phytoplankton communities through selective toxicity of pollutants have been observed in the laboratory<sup>5</sup> and in freshwater ponds<sup>6</sup>. The predictions, based on laboratory research, suggesting that pollution-linked alterations in the species composition of phytoplankton communities would result in disturbances of zooplankton communities<sup>5</sup> (due to selective herbivory) are consistent with the observations described by Reid<sup>1</sup>. The degree to which the North Sea plankton are exposed to industrial wastes is subject to further study, though plankton in neighbouring waters are highly contaminated with organic pollutants<sup>7,8</sup>. (It is interesting that sublethal concentrations of pollutants can interact with various environmental factors to enhance pollutant toxicity to marine organisms, including phytoplankton.) Furthermore, North Sea animals higher in the food chain are heavily contaminated with industrial waste products<sup>9</sup>, indicating their general presence in the resident biota.

Longhurst *et al.*<sup>10</sup>, citing the natural variability of marine populations, commented that changes in oceanic plankton communities often cannot clearly be traced to marine pollution. Indeed, it is difficult to pinpoint any single environmental factor as the sole cause of community disruptions, because so many variables may interact to affect biological systems. I propose that the presence of persistent pollutants be considered one of the possible contributing factors influencing the plankton communities in the North Sea.

# reviews

THIS book\* gives an account of the famous encounter between Lord Kelvin and the geological establishment over the use of physical arguments to set limits to the age of the Earth. It was an epic struggle which continued for 50 years with great vehemence and some acrimony.

In their thoughts about time the geologists of the middle of the nineteenth century were not much inclined to arithmetic. They had inherited from Hutton and Lyell the idea that the Earth showed "no vestige of a beginning, no prospect of an end". This and the related ideas, that things have always been much as they are now, and that causes at present at work could, given enough time, account for all that has ever happened on earth, were the basis of their science and, in large degree, still are.

Very early in his career Kelvin became interested in the time scale of the Earth. His two principal methods of setting an upper limit were the calculation of the time for which the earth's original heat could supply the outward flow observed at the surface and a similar calculation for the sun. Both calculations required few and very plausible assumptions. Kelvin, and most physicists of the time, had great confidence in the results.

Kelvin's first estimate of 100–400 Myr did not greatly alarm the geologists. They no doubt knew that 100 Myr was a finite time, but it was so large a number that it seemed unnecessary to quarrel with it. Unfortunately, as he grew older, Kelvin grew more parsimonious of time and reduced his estimate to 20–30 Myr with threats of further restriction. This was too much, or rather too little; the few geologists who had disliked the 100 Myr limit were joined by the majority of their colleagues and a classic encounter occurred between two groups with almost no ideas in common. Kelvin had the prestige of physics, of Newton and of the divinely prescribed order of Nature behind him. Clearly he could not be wrong. The geologists had gut feelings that any specified length of time was inadequate, but little pos-

sibility of convincing others. Darwin, for example, estimated the time necessary to excavate the Weald of Kent as 400 Myr, but had no real basis for his statement, which he came greatly to regret.

## Epic struggle with geological establishment

Edward Bullard

The story of the collision of two such disparate groups is admirably told in this book. Besides the main contestants all kinds of fascinating figures flit across the scene, including Lord Salisbury (the Prime Minister), Clarence King (the explorer of Colorado and Utah), T. J. J. See (the presumed author of that once celebrated work, *The Life and Remarkable Discoveries of T. J. J. See*) and even, briefly, Frank Harris (the author provides a reference to his *Life and Loves*). The course of the dispute is

set out in detail and is of great interest to anyone concerned with the development of ideas about the Earth. Here the ideas of stratigraphy, evolution and physiography first met theoretical physics. The interest is, of course, enhanced by the fact that the biologists and geologists were right in saying that 30 Myr was not enough time, even though they had no way of providing convincing numerical estimates; how could one say how many years it took to convert *Eohippus* into a Derby winner?

The debacle induced by the discovery of radioactivity is well described; one of the oddest features is that no one seems to have been much concerned that, for the next 30 years, there was still no convincing account of the source of the Sun's heat.

In spite of the careful account of all these things some readers may feel a little deprived. An historian must study the past in its own terms. He must not ask 'What was Henry VIII's attitude to women's lib?'. This viewpoint has been adopted also by historians of science and, in some degree, is clearly necessary. But should one go the whole way? The author of this book consistently refrains from saying that anything is right or wrong, silly or unjustified. If Kelvin assumes that the Earth was initially at 1,500 °C, the author reports that he said it and that it was a more or less arbitrary choice, but he does not add that it matters very little what figure is taken. On the other hand no one would guess that Kelvin's assumption of the absence of convection within the Earth was crucial and that the attacks on it were well based. The history of science is different from other kinds of history; there is the additional fact that some things are correct and some wrong *sub specie aeternitatis*. The reasons for the beliefs are a function of the surrounding culture, but being right or wrong is not a thing of one age alone. In the study of the motions of the planets Descartes was wrong and Newton was right, and so it will always be. It is part of the function of the historian to say how and why. We and he lose a good deal if he backs away from the question. There were geniuses, inspired guessers, cranks, stick-in-the-muds and rash men in the past, just as there are today, and it is a pity to treat them all alike and leave the reader to decide which is which. □

\**Lord Kelvin and the Age of the Earth*. By Joe D. Burchfield. Pp. xii+260. (Macmillan: London and Basingstoke, July 1975). £10.

## Metallic catalysts

*Structure of Metallic Catalysts.* By J. R. Anderson. Pp. ix+469. (Academic: New York and London, June 1975.) £12.60; \$33.75.

THE technical importance of catalysts is such that an understanding of their structure is of obvious importance, whether from the view-point of the extent of surface accessible to reactants, or of the more intimate details of surface topography, chemistry, or electronic structure which might influence adsorption processes. Also, in the case of supported catalysts, the structure of the substrate can determine the state of dispersion of the metal and perhaps contribute to the overall reaction. This book is the first attempt to bring together information in these areas from the plethora of published literature, and from this aspect alone is a considerable achievement.

Available information on the structure of typical metallic phase catalysts is covered in some detail, particularly that relating to model systems where

surface contamination can be more carefully controlled and which can therefore be used as standards for comparison. There are chapters on supports, massive, and dispersed, metal catalysts, and the structure and properties of small metallic particles. The book concludes with an outline of some appropriate techniques for the physical and chemical investigation of such structures, and there is an appendix which describes the preparation of some examples of typical metallic catalysts.

The state and scope of the subject dictate that the work be largely descriptive and of a review nature. It is, however, well and critically written, acceptably illustrated, and generally readable. It should make an admirable starting point for those entering the fields of catalysis or surface chemistry; the wealth of detail, some of it in useful tabular form, and the large number of quoted references, unfortunately without an author index, will also make it a useful addition to the libraries of any academic or industrial laboratory engaged in similar studies.

G. K. L. Cranstoun

## Opiate receptors

*Opiate Receptor Mechanisms: Neurochemical and Neurophysical Processes in Opiate Drug Action and Addiction.* (Based on a work session of the Neurosciences Research Program.) By Solomon H. Snyder and Steven Matthysse. Pp. 116+vi. (MIT Press: Cambridge, Massachusetts and London, June 1975.) \$8.95.

THIS book is a record of a Work Session of the Neurosciences Research Program sponsored by the Massachusetts Institute of Technology and held in Boston during May 1974. The symposium was an unqualified success because it came at a time when the work of several groups, particularly those of A. Goldstein, L. Terenius, S. H. Snyder and C. B. Pert, and E. J. Simon, had greatly contributed to our knowledge of the nature and distribution of opiate receptors.

When the symposium was planned, various lines of indirect evidence had accumulated which suggested that there were in the central nervous system endogenous ligands that interacted with the opiate receptors. Evidence for the existence of such ligands was presented by L. Terenius, and by J. Hughes and H. W. Kosterlitz. G. W. Pasternak and S. H. Snyder mentioned supporting evidence which was updated in the published version.

These two sections are probably the most topical parts of the book. In the introduction, there is a brief review of the chemistry and action of opiates for readers unfamiliar with the field. The second chapter of the book deals with the biochemical identification of opiate receptors and the third with agonist-antagonist interactions. The fourth considers neural mechanisms and contains a discussion by D. J. Mayer of the interesting experiments on analgesia induced by electrical stimulation of the periaqueductal grey matter and its prevention by the opiate antagonist, naloxone. The fifth chapter deals with biochemical phenomena in opiate action and addiction, the sixth with addiction, the seventh with the discussion review on further research. The final chapter is a stimulating and provocative essay by S. H. Snyder on a model of opiate receptor function with implications for a theory of addiction.

This is a well-produced book presenting expertly and critically the state of our knowledge in an important field. Because the various chapters are not written by the individual authors but by the editors with the help of a small number of participants, the style is uniform and pleasing. It is unavoidable that part of the book has already been overtaken by events in a field in which a considerable number of workers are in constant and vigorous competition with each other.

H. W. Kosterlitz

## Hydro, azo, azoxy

*The Chemistry of the Hydrazo, Azo and Azoxy Groups.* Edited by Saul Patai. Part 1: Pp. xiv+1-598. Part 2: Pp. xiv+599-1,190. (Wiley/Interscience: London and New York, September 1975.) £17 each part; £33 two volume set.

THIS is the sixteenth volume to appear in Professor Saul Patai's monumental series on the chemistry of individual functional groups; there are five volumes to come. There is no detailed consideration of azo dyes on grounds of space, and diazonium salts and diazoalkanes are to be covered in a subsequent volume.

The general style, arrangement and coverage closely parallel those of previous volumes, including the usual articles on structure, thermochemistry, electrochemistry, photochemistry, radiation chemistry, mass spectra, basicity and complexing, of the three groups. There are also interesting accounts of chiroptical properties, directing and activating effects, biological formation and reactions, syntheses and uses of isotopically labelled species, rearrangements (a particularly good and interesting contribution), ionic reactions, and radical reactions. There is a useful chapter on preparative procedures, and also two interesting longer chapters on oxidation and synthetic uses, and reduction and synthetic uses, of the groups. Finally there are more specific, and specialised items on transition metal chemistry of the groups, on conformational analysis of hydrazines, and a long but very interesting chapter on the formation and fragmentation of cyclic azo compounds.

The literature seems in general to have been surveyed to the end of 1973—I could find only fourteen references, out of many hundreds, dated 1974—although this datum line does not seem to be uniform for all articles. The subject index could usefully have been a little more comprehensive, perhaps at the expense of the author index that one would have thought to be relatively less important. The general printing and layout of the reaction schemes is markedly superior to that in most of the previous volumes.

Peter Sykes

**Erratum.** Gordon and Breach, publishers of *Composition of Cosmic Radiation* by Apparao, reviewed jointly with another book on the same subject (*Nature*, 258, November 6, page 40), point out that the reviewer's statement about the comparative prices per page of the two books is incorrect. The book by Apparao has, in fact, the lower price per page. We apologise for the error.

*Interfacial Phenomena in Metals and Alloys.* By Lawrence E. Murr. Pp. xiv+37. (Addison-Wesley: Reading, Massachusetts, and London, September 1975.) Cloth \$24.50; Paper \$14.50.

THE five chapters of this book make up a comprehensive treatment of those aspects of surface science which contribute to the properties of materials, and in particular to metals and alloys. The first is concerned with surface thermodynamics of solid surfaces, starting from Gibbs' model, but including a discussion of the distinction between surface stress and surface tension, and the effect of vacancies and other singularities of structure. In the second chapter these principles are applied to the description of conditions for the establishment of interfacial equilibria, especially the evaluation of interfacial free energy ratios. Because of the crucial importance of interfacial free energy values in determining the forms of crystals and grains, chapter 3 is concerned with their determination in different systems. The last two chapters treat the structure and properties of interfaces respectively.

A particular feature of this book is the wealth of factual information which has been gathered into tables of surface and interfacial free energies of solids, and related quantities, occupying almost 10% of the available space. Taken with over 800 references, this ensures that the book will be extremely useful as a source of critically appraised facts for research workers in addition to its primary function of instructing students of materials science in important principles, and exercising them with fifty problems, mostly numerical. Comprehensive author and subject indexes have been provided, and the book is very clearly printed and copiously illustrated. **A. Couper**

*Organoborane Chemistry* (Organometallic Chemistry: Series of Monographs.) By Thomas Onak. Pp. x+360. (Academic: New York, San Francisco and London, July 1975.) \$38.00; £18.25.

THIS book is one of an important series on organometallic chemistry, edited by P. M. Maitlis, F. G. A. Stone and R. West. The topic of organoboron chemistry has developed very rapidly: this is the first review for almost ten years dealing explicitly with compounds having boron-carbon bonds, although others are available

on related topics, such as hydroboration. Excluded are other organic boron compounds such as boron esters.

A brief introduction (1 page) is followed by Chapter 2 (18 pages), concerned mainly with X-ray, spectroscopic, and thermodynamic data. Chapter 3 (116 pages) deals with methods of B-C bond formation and cleavage. [For those familiar with the field it will be clear that the author has used a very similar presentation to that used in my article in Muetterties' monograph of 1967.] Chapters 4-6 (80 pages), on four-coordinate organoboranes, organodiboranes, and other polyboranes, are particularly welcome.

## Books brief

There are nearly two thousand references which include papers published in 1973. Inevitably, therefore, the discussion is selective, particularly as about a quarter of the 224 pages of text is taken up by tables. Nevertheless, the monograph is informative and well-written and should be essential reading for anyone active in this field. **M. F. Lappert**

*Interactions on Metal Surfaces.* (Topics in Applied Physics, Volume 4.) Edited by R. Gomer. Pp. xi+310. (Springer: Berlin and New York, 1975.) DM78; \$33.60.

THIS book contains seven articles on selected aspects of the chemisorption of gases on metals. A model (chapter 1) consisting of an alternating potential within the metal and a discontinuity at the surface enables the calculation of wave functions near the surface using generalised Wannier functions. The electron work function is then calculated from a continuum model into which the effect of crystallinity is introduced as a perturbation, and adsorption as localised screening. The chemisorption bond (chapter 2) is described initially in terms of an LCAO-MO model, which is extended to include overlap between metal and adsorbate states and lateral interactions.

Four chapters then give an account of experimental aspects of chemisorption, the first summarising studies of

clean surfaces and adsorption using a variety of techniques, whereas the other three discuss thermal and electron impact desorption, photoemission and field emission spectroscopy, and low energy electron diffraction. The final chapter on heterogeneous catalysis is included to indicate, in the editor's words, "that there is more to interactions on surfaces than the adsorption of hydrogen on the (100) plane of tungsten".

There is some overlap in subject matter between the chapters, but each presents its author's individual view of recent advances. There are over 700 references, a useful index and many excellent illustrations. It is clearly not a 'first text-book' of chemisorption, but research workers will find it both stimulating and informative. **A. Couper**

*Genetics and Psychopharmacology.* (Modern Problems of Pharmacopsychiatry, Volume 10.) Edited by J. Mendelewicz. Pp. viii+132. (Karger: Basel, London and New York, 1975.) Sfr.58; DM55; \$24.25.

PSYCHIATRY relies on a wide range of investigational techniques ranging from the psychoanalytical to the biological. Among the latter, genetic studies have suggested that many major psychiatric illnesses have a hereditary component. The introduction of effective drugs for these illnesses has emphasised the importance of biological factors in the causation and mechanism of psychiatric illnesses. In this book, the two threads are drawn together. The points of contact, however, remain few and one or two of the contributions in this multi-author book contain little or no genetics. The chapters are of a generally high standard and range widely from the role of heredity in alcoholism to the genetic mechanisms governing the rate of acetylation of the monoamine oxidase inhibitor, phenelzine. Monoamine oxidase is the main interest of almost half the book but claims that levels of this enzyme in blood platelets are abnormal in patients with depression and schizophrenia and in relatives of the latter seem premature. Brain levels (surely more relevant) are quite normal in psychiatric patients. One is left wondering whether the greatest difficulties in biological psychiatry relate not to the biological techniques but to the unsystematic way in which diagnoses are made and symptoms assessed. **M. H. Lader**

# obituary

The malariologist **Meir Yoeli** died suddenly on December 5, 1975 in New York. He was born in Lithuania in 1912 and graduated with an M.Sc. from the University of Kaunas in 1934. Soon afterwards, he fled to Palestine and was appointed a lecturer at the Hebrew University of Jerusalem in the department of tropical medicine. Here he was introduced to the subject of malaria by two great masters—Gideon Mer and Saul Adler F.R.S., and continued this work in 1938, in a year's study with Missiroli and Angelini in Italy. Yoeli received his MD at Basel in 1939, and served under Colonel George Macdonald as a malariologist with the R.A.M.C. in World War II. Some years after the war, he left Israel for the United States of America, where he obtained an appointment in the Department of Preventive Medicine of the University of New York, and where he continued to work until his death.

Yoeli is best known for his research in rodent malaria. He had set his heart on solving the problem

of the life cycle of these parasites—a problem which had defeated many other investigators. He first succeeded in transmitting *Plasmodium berghei* through the mosquito in 1951 at the London School of Hygiene and Tropical Medicine, but it was another 13 years before he discovered the clue for producing viable infective forms (sporozoites): the secret of success lay in dropping to 19 °C, the ambient temperature in which his infected mosquitoes were kept—the same temperature at which natural transmission occurs in the cool highland forests of Zaire. This unexpected result was followed by another, equally spectacular—the rapidity of the exo-erythrocytic cycle of the sporozoite in the rodent's liver (2 d instead of the usual 8 d in primate malaria). Much of this work was done in collaboration with his Belgian friend—the late Professor Ignace Vincke—who was the original discoverer of rodent malaria in 1948. Yoeli extended his research to the immunological aspects of the infection, and recently made important contri-

butions to the aetiology of leukaemia.

Yoeli was as interested in art as he was in science. In 1974 he became an honorary member of the Hellenic society for the History of Medicine, and only his premature death prevented a compilation of his Hebrew poetry, literature and philosophy for publication. He will be greatly missed by his family and his friends all over the World.

**P. C. G. Garnham**

**Dr James Linzell** died on December 28, at the age of 54. After qualifying and working as a vet, he obtained his Ph.D. at Edinburgh in 1951. He spent the rest of his career in the Institute of Animal Physiology in Cambridge, where he became the Head of the Department of Physiology.

His major interest was the physiology of the mammary glands of farm animals, and his discoveries about the mechanisms for the starting of, supply to and production by these organs underpin the present understanding of the subject.

## announcements

### International meetings

March 1–4, **Breast feeding and the mother**, London, The CIBA Foundation, 41 Portland Place, London W1N 4BN, UK).

March 1–5, **Tunnelling '76**, London (The Secretary, Institution of Mining and Metallurgy, 44 Portland Place, London W1N 4BR, UK).

March 1–5, **Oilseed and vegetable oil processing technology**, Amsterdam (World Conference, AOCS, 508 S. Sixth Street, Champaign, Illinois, 61820).

March 1–5, **Analytical chemistry and applied spectroscopy**, Cleveland (Dan P. Manka, Program Chairman 1976, Jones and Laughlin Steel Corporation, Graham Research Laboratory, 900 Agnew Road, Pittsburgh, Pennsylvania 15230).

March 2, **Applications of linear free energy relationships in biological systems**, London (The Assistant Secretary, Society of Chemical Industry, 14 Belgrave Square, London SW1X 8PS).

March 2–3, **The working diver**, Colum-

bus, Ohio (Debra Klamforth, Battelle, Columbus Laboratories, 505 King Avenue, Columbus, Ohio 43201).

March 9–13, **Physics in industry**, Dublin (Eon O'Mongain, Organising Secretary, Physics Department, University College, Dublin, Ireland).

March 15–19, **Third international conference on culture collections**, Bombay (Professor F. Fernandes, Chairman, Local Organising Committee, Bombay University Club House, B. Road, Churchgate Reclamation, Bombay 400020, India).

March 17–18, **The semi-arid areas of the world**, London (The Executive Secretary, The Royal Society, 16 Carlton House Terrace, London SW1Y 5A9, UK).

March 22–23, **Information for the water industry**, Reading, UK (The Conference Organiser, Water Research Centre, Medmenham Laboratory, PO Box 16, Ferry Lane, Medmenham, Marlow, Bucks SL7 2HD, UK).

March 22–23, **Genetic engineering**, Glasgow (Dr P. J. Goddard, Organising Secretary, Nucleotide Group

Meeting, Department of Biochemistry, University of Glasgow, Glasgow G12 800, UK).

March 23–26, **Fundamental and applied dosimetry**, Saclay, France (M. Y. Le Gallic, Secrétaire général du VIII<sup>ème</sup> Congrès International de la S.F.R.P., C.E.N. Saclay, B.P. n° 2,91190, Gif sur Yvette, France).

March 25–26, **The controversy about sweeteners**, Washington, D.C. (Barbara Jorgensen, NAS Office of Information, 2101 Constitution Avenue, N.W., Washington, D.C. 20418).

March 26, **Fish farming**, Edinburgh (The Executive Secretary, The Royal Society of Edinburgh, UK).

March 28–April 1, **International symposium on fluorescein angiography**, Ghent (Secretariat, c/o Holland Organising Centre, 16 Lange Voorhout, The Hague, The Netherlands).

March 29–April 1, **International symposium on urinary stone formation**, Davos, Switzerland (Professor H. Fleisch, Department of Pathophysiology, Murtenstrasse 35, CH- 3008 Bern, Switzerland).

January 22, 1976

## Negotiate flexibly, but explain publicly

THE Royal Commission on Environmental Pollution, chaired by Sir Brian Flowers, has just reported on air pollution control (Cmnd 6371, HMSO, £1.75) and manages to handle the potentially inflammatory issue of the Alkali Inspectorate in a sensible and pragmatic way. The inspectorate is praised and criticised in about equal amounts, but no major modifications are proposed to its traditional mode of working, namely by collaboration with industry rather than by confrontation.

Air pollution control in Britain is carried out through two very separate administrative machineries. Her Majesty's Alkali and Clean Air Inspectorate is charged with overseeing a limited number of specified processes deemed to be particularly polluting or problematical. (The first of these processes was initially associated with alkali works where, from 1820 on, great clouds of hydrochloric acid gas were released in the manufacture of sodium carbonate from salt—hence the quaint name given to the inspectorate when it was established in 1863.) Inspectors have always worked on the principle that industry should use the “best practicable means” to reduce discharges rather than be held to fixed emission standards. In the course of this, the inspector has played a substantial and unsung role in the rapid transfer of information about anti-pollution technology, and has also been consulted as a matter of course before the installation of new plant. But in spite of continued advances in freeing the air of industrial pollutants, the inspectorate has come in for plenty of criticism. The “best practicable means” approach, its critics allege, can hide all sorts of abuses or agreements to go easy on polluters. The inspectorate has compounded the problem by making inadequate responses to its detractors, partly, no doubt, because inspectors feel themselves constrained by industrial secrecy and partly because staff numbers are only adequate to perform the inspecting job, not to hold colloquia or confrontations with a broader public.

The other means for controlling air pollution is through the local authority, whose environmental health officer must take care of domestic pollution and of those industries not on the inspectorate's list. Some authorities have air pollution units, but many do not, so control is patchy. Relations between the inspectorate and local authorities vary from good to bad (there is no administrative reason why they should ever meet). And for all that some cities have cleaned up the air dramatically over the past 20 years (London now has 70% more sunshine in December than it used to before smokeless zones were introduced), 40% of the nation's premises which were originally planned to be in smoke control areas have still to come under this constraint.

It is the commission's hope that by releasing the inspectorate from the Health and Safety Executive, where it never really belonged, and by subsuming it in a larger Pollution Inspectorate which could deal with other problems such as water pollution and solid waste, the necessary central expertise can be preserved and augmented while making it easier for local authorities to deal with this expertise. This depends on two fairly important assumptions: first, that the major problems in water and solid waste management are amenable to the same sort of negotiation that the inspectorate has evolved for air pollution. There seems no reason why they shouldn't be if a national unit is put together from existing staff in water authorities, central government and so on, but positive results may still be several years off. Second, the Pollution Inspectorate really must take its relations with the public seriously and must hire people appropriately. It cannot simply be allowed to become an expanded Alkali Inspectorate, full of very dedicated experts, employed full time in talking to industry; at least 20% of the staff should be available to talk and listen regularly to the public.

The commission talks of the housewife whose washing has been dirtied by a breakdown in pollution control at a nearby plant and who may be “disconcerted and irritated” by a request to leave a message on the District Alkali Inspector's phone answering machine (inspectors only have part-time secretarial staff!). She might be lucky even to find the right phone number. In the London Phone Directory there is nothing under “Air”, “Alkali”, “Clean Air”, “Clean Air Council” (which advises the government on air pollution), “Her Majesty's Alkali and Clean Air Inspectorate”, or “Pollution”. A very smart housewife might just possibly alight on “Environment, Department of the”, where lurking under a sub-sub-heading is “Noise, Clean Air and Waste”. Or she might try her local authority for which, if the phone book is not too out-of-date there could be an entry “Environmental Health Services”, but no mention of air pollution. But, of course, if it was smoke from a bus she would have to ring London Transport. And what about smoke from a car?

Nowhere is bureaucracy more anonymous than in the phone book. The first job for a new pollution inspectorate might be to follow the example of some other countries, hire some intelligent telephone-persons and put a number in the directory with the entry

AIR POLLUTION from all sources—  
complaints and queries . . .

No charge for this public service . . .

# Planning to use science . . .

*Vera Rich looks at the Soviet Union's recently published Five Year Plan, in which the prominence usually accorded to science and technology is again apparent.*

AS EXPECTED, the Soviet Union's Five Plan for the period 1976–1980, soon to be submitted to the party congress, gives top priority to greater efficiency throughout the economy, specifically in agriculture and industry. But the framework of the Plan as a whole considerably curtails the almost rhetorical aims for science also expressed by the Plan—namely, “the further expansion and deepening of investigations of the laws of nature and society, increasing its contribution to the solution of problems of current importance in the construction of the material and technological basis of communism, accelerating scientific and technical progress and the growth of effectiveness of production, increasing the well-being and culture of the nation, and shaping the communist outlook of the workers”.

The Plan's modest targets for growth, investment and production seem to have been set deliberately low to take into account possible set-backs of the sort that hampered the previous Plan, such as crop failures and inefficiency. The target for national income growth, at 24–28%, is lower than the 28% achieved by the 1971–1975 Plan. Industrial production will rise 35–39% as against 43% previously, while the growth of investment in agriculture is to fall from 60% to 30%. Under the general slogan of improved “quality” and increased production, it is demanded that 90% of industrial growth and all the growth in agriculture and production is to be met by higher labour productivity (as opposed to 80% in the previous plan).

Within this general prospect of harder and better work with no encouragement of major initiatives, which is seen by many as the design of ageing politicians whose active lifetime is unlikely to run to the full term of the Plan, the scientific projects selected for specific mention and encouragement form an interesting cross-section of research. At one end the emphasis on pure and applied mathematics is related in the Plan to the need for the more efficient and extensive computerisation of the economy—growth in the computer and automated equipment sections, at 60–80%, far outstrips the anticipated average for the industrial sector as a whole, and there are calls for cuts in the share of manual labour in production

At the other end there is the use of space research for the study of natural resources, meteorology and navigation, and for “other needs of the national economy”. Nuclear, plasma, solid state and low temperature physics also receive special mention, as do quantum electronics, optics and astronomy; the need for new materials is stressed, especially magnetic semiconductors, superconductors, and “technically valuable” crystals, and the whole physics programme is grouped in the Plan with the need to develop atomic power and other new sources of energy. Indeed, energy-selected industries, including the chemical and petrochemical sectors, will be among the fastest-growing. The 1980 oil target is up 27%, and a rise of 42% in natural gas will enhance the country's potential as an energy exporter.

In a similar manner, the biology programme is linked both to the need to develop new crops and improvements in occupational health. The main aims for agriculture include the development of animal husbandry and the fodder base, but there will be strong pressures for an improvement in agricultural productivity.

To a certain extent, such elaborations of the purposes of research projects in a time of financial cut-backs may be considered as a justification for their continuation. But the problem with Soviet science, which for all the latitude its practitioners possess operates within a rigid system of state planning, is more complex. With only limited resources of labour and capital available, certain projects—the space programme, for example—acquire a favoured position over others as a result of a complex decision-making process in which potential defence applications or international prestige can be important.

Apart from enjoying considerable material benefits, scientists working in these areas usually find few obstructions in the pursuit of their work. It is possible, for example, to order equipment from abroad; and the procedures for obtaining experimental materials are considerably facilitated. As a result, these fields inevitably attract a great majority of the most gifted talent. On the other hand, scientists not working in a “favoured” field find themselves at a considerable disadvantage, at least with respect to the bureaucracy: requisitions for experimental materials

must be made far in advance and often can only be fulfilled by an unofficial exchange of surpluses between laboratories or institutions.

The gap between favoured and non-favoured projects and institutes tends to widen as a result, and once a particular subject, say space research, has acquired a measure of prestige, a major cut-back is more difficult to order, at least in the political life-time of those who first sanctioned it. As for the non-favoured projects, these tend to be staffed by the relatively less able, resulting in a relative decline in performance, so that in certain fields, like precision instruments, a technological short-fall emerges which makes the purchase of required equipment abroad more likely.

Accordingly, although throughout the Soviet Union's history the presumption has been that Soviet science must inevitably outstrip that of the west, the day of total independence of Soviet technology still lies in the future. This is tacitly admitted by the present plan, which includes the purchase from the west of equipment for producing mineral fertilizers and for the development of the oil, gas, paper, cellulose, and “certain other” industries. The stress on the need for computerisation and automation suggests that there will be considerable (if unacknowledged) reliance on western know-how.

One possible solution open to the authorities is the purchase of foreign equipment which can then be studied and reproduced, thus saving research and development costs. The Plan's proposals may therefore be a disguised way of purchasing expertise. During the last few years the Soviet Union has signed a number of agreements on technological cooperation with Western countries which are clearly intended to be of bilateral benefit, and it will be interesting to observe how the fields of cooperation may change in the future as the Soviet Union closes the short-fall gap in this or that branch of technology.

The sensitive relationship between science and industry in the Soviet Union will continue to be revealed over the coming five years. In the short term, because the rigid targets imposed on industry often leave no time for re-tooling or re-equipping, the introduction of some cost-saving and efficient new process may be reflected in the quarterly returns as a falling-off in various industries. The contribution of science to the long term aims of higher productivity and improved efficiency, to be effective, will demand better management and planning of techniques. Yet, oddly, this is a comparatively neglected area in the new Five Year Plan. □

## ... in public or private?

*Colin Norman in Washington examines the arguments which two recent events involving Soviet dissident scientists have helped to regenerate in the USA's scientific community.*

ON DECEMBER 12 last year, Sergei A. Kovalev, a Soviet biologist, was convicted of "anti-soviet agitation and propaganda" and sentenced to seven years in prison with hard labour, to be followed by three years of exile. His offence was that he had spoken out in defence of human rights and disseminated outlawed literature. Although he had been in jail for nearly a year waiting trial, Kovalev's plight raised little outcry in the West.

In contrast, early this month Leonid I. Plyushch, a mathematician, was released from a psychiatric institution in which he had been forcibly detained for nearly three years, and allowed to leave the Soviet Union. Plyushch's incarceration, for offences similar to those charged to Kovalev, had provoked many public protests from groups in the West, including scientific organisations and the French Communist Party.

To many observers here, those two events underline a simple and obvious fact—public outcry in the West can play a decisive role in tempering the Soviet government's repression of so-called dissident scientists and intellectuals. And that is precisely why the National Academy of Sciences, the most prestigious scientific organisation in the United States, is being pressured to make more public representations on behalf of individual scientists in the Soviet Union, and to speak out more forcibly in defence of human rights.

Although a few individuals have long urged the Academy to adopt a more aggressive public stand on such matters, the issue has recently received some publicity because of an open dispute between the Academy President, Philip Handler, and Jeremy J. Stone, Director of the Federation of American Scientists (FAS), a liberal organisation with a membership of 7,000 which lobbies for such causes as arms control.

The dispute centres on a brief item in the December issue of the FAS newsletter, in which Stone related three complaints about the Academy's public posture in regard to Soviet dissidents, which he heard directly from beleaguered Soviet scientists. Stone picked up the complaints during a recent visit to the Soviet Union on behalf of the FAS to investigate the problems faced by Soviet scientists who have criticised official policies or who

have applied for exit visas; he printed the complaints as part of a detailed account of his findings.

Handler was incensed by Stone's reporting of the complaints because he claims that it represents a gross distortion of the Academy's actions. He fired off an angry, eight-page letter to the FAS president, Philip Morrison, defending the Academy's record, accusing Stone of an "ugly act", and demanding an apology. Beneath the anger, however, lies a serious issue, namely, what is the best way in which the Academy can use its prestige to seek relief for harassed Soviet scientists, or for scientists in similar predicaments elsewhere in the world?

The Academy operates a number of scientific exchange agreements between the United States and other countries, a fact which gives Academy officials extensive contact with their counterparts in the Soviet Academy of Sciences. In the past few years, those contacts have been used occasionally for private, face-to-face representations by the Academy to seek relief for individual Soviet scientists who have been harassed, dismissed from their jobs or imprisoned for such offences as applying for visas to emigrate to Israel, criticising Soviet policies or speaking up in defence of human rights.

In 1972, for example, during a visit to Washington by M. V. Keldysh, then President of the Soviet Academy of Sciences, Handler and other Academy officials took the opportunity to protest the imposition of hefty exit taxes on scientists who had applied for emigration visas. And early in 1973, during a visit to Moscow, Handler made repre-

sentations on behalf of Benjamin Levich, an eminent Soviet electrochemist who had been fired from his job after applying for a visa to emigrate to Israel. Handler says he took up Levich's case with Keldysh and President Podgorny, and he even asked Keldysh to deliver a letter to Levich awarding him a prize from the American Electrochemical Society and inviting him to the United States to give a lecture. Keldysh refused to accept the letter and accused Handler and the Electrochemical Society of "playing politics".

Handler was therefore particularly incensed by one of the complaints in the FAS newsletter, that during his visit to Moscow he had snubbed Levich by refusing to meet him. Handler said that Levich in fact telephoned him at his hotel an hour after he arrived and invited him to his house. Handler says he refused because such a visit would blunt the impact of his private negotiations on Levich's behalf, a position which is consistent with his view that the Academy should conduct such negotiations in private, without making a public fuss. Similar sentiments are expressed by George S. Hammond, the Academy's Foreign Secretary. Hammond says that "having chosen the quiet diplomacy approach, I think we should stick to it. If we go to Moscow and hold private discussions and then make public statements, it would be a breach of confidence and undermine our position".

Stone, however, takes a different view. "All of my Soviet experience during six visits," he says, "suggests that complaints made in private are often ignored, while those made publicly must be dealt with." As far as Handler's refusal to visit Levich is concerned, Stone notes that because of the publicity which would have attended such a visit, "I have no doubt that Levich was more interested in having Handler visit him while he was in Moscow than in any representations that Handler could have made for him privately".

The Academy has, however, made one very public protest. In September 1973, when the press campaign against Andrei Sakharov was at its height, Handler sent a sharply worded protest to Keldysh, warning that unless harassment of Sakharov ceased, scientific co-operation between the United States and the Soviet Union could be jeopardised. Shortly thereafter, the press campaign abruptly stopped. Though Sakharov has, of course, come in for more criticism and intimidation since, it is widely believed that he is no longer in imminent personal danger. According to Pavel Litvinov, a Soviet physicist who was exiled to Siberia after protesting against the Russian invasion of

Jeremy Stone, FAS Director

Czechoslovakia, and who is now living in the United States, "the representation by the National Academy of Sciences in the case of Sakharov was effective. Of that I am sure". He added that "in every case when the Soviet bureaucracy has given in, it has been done by open pressure". Handler maintains that the public protest on Sakharov's behalf was made in response to a critical situation—the fear that Sakharov was about to be arrested and tried for treason. He suggested that such an approach should not be used in less dramatic situations.

Stone believes, however, that the initial success of the Sakharov protest should convince the Academy that occasional public protests would greatly strengthen its hand in private negotiations. And Lipman Bers, an Academy member and President of the American Mathematical Association who has made representations on behalf of beleaguered scientists in several countries, notes that "my impression and experience is that so-called quiet diplomacy and public protests reinforce each other". Similarly, Harrison Brown, a former Foreign Secretary of the National Academy of Sciences who played a key role in the Academy's protest over Sakharov, suggests that "if anything, the Academy has erred on the side of not doing enough publicly", though he adds that he believes that the private approach "has tempered Soviet actions" and notes that "it is very difficult to get a proper balance between public and private approaches".

Stone, meanwhile, is working to get the prestige of Academy members behind some public protests to be launched by the FAS on behalf of dissident Soviet scientists. Last month, he sent a letter to every member of the Academy, asking whether they would be willing to lend their support to petitions "for scientists being denied the right to function as scientists". He said last week that he anticipates a positive response from about 25% of the Academy's members. In addition, he has circulated a petition among physicist members of the National Academy of Sciences asking for their support for Andrei Tverdokhlebov, a physicist who was arrested nine months ago for allegedly disseminating false material and whose trial is imminent. A very high proportion has already responded. A petition has also been mailed to some 20,000 biologists in support of Kovalev. Stone also attempted, unsuccessfully, to ensure that international observers would be allowed at Kovalev's trial.

The Academy is therefore under some pressure to take a more aggressive, public stand in support of dissident Soviet scientists. It should be noted, however, that such a move would draw

strong criticism from the State Department and other government agencies since it would seem to run counter to the spirit of detente. The Administration would much prefer a quasi-government body like the Academy to work behind the scenes, leaving the public protesting to private organisations like the FAS.

The issue of how learned societies should handle relations with their

counterparts in the Soviet Union has, of course, also been aired in other countries. In the UK scientists debated the subject on television in 1973, and in 1974 the Council of the Royal Society considered the issue following an initiative by Professor John Ziman. The continuing low profile of the society makes it reasonable to assume that proposals for a more public stance were turned down. □

## An appeal for help

THE following quotations are taken from a letter written by Valentin F. Turchin, a Soviet mathematician who was fired from his job in July 1974 after he had made a public statement in defence of Andrei Sakharov. Turchin, who is chairman of the Soviet group of Amnesty International, has been out of work for 18 months, and has applied for permission to visit the United States to work at Columbia University. He was informed on December 15 that his application had been denied. The letter was received on January 13 by Jeremy Stone, the FAS Director. Turchin says that he wants it to be discussed by the scientific community in the West. It will eventually be published in full by the Khronika Press in New York.

Turchin begins by describing the harassment and the trial last month of Sergei Kovalev. Kovalev, an eminent biologist, was given the maximum sentence of 7 years' imprisonment with hard labour and a further three years of exile within the Soviet Union for "anti-Soviet agitation and propaganda". Noting that, together with Sakharov, he had appealed for help for Kovalev from Western scientists, Turchin states that "there was no response deserving to be mentioned and I don't know whether there was any response at all . . . No action was made which could have attracted serious public attention and influenced Soviet authorities. The world scientific community betrayed Kovalev".

He continues: "You are very proud, my dear colleagues, that you separate science from what you call politics. You do not go in for politics, you say. Neither do we. Dissidents in the Soviet Union do not go in for politics: they struggle for air. What you are separating science from is not politics but mere decency. And in fact, it is not separation, but a reversal, changing of the sign. For whatever you think, you are not neutral in the conflict between totalitarianism and freedom. You actively cooperate with totalitarianism, support it . . .

"People of science are intrinsic enemies of totalitarianism, because they professionally need intellectual freedom. The core of the Soviet dissidents consists mainly of scientists. But the state presents to the scientist a dilemma: either to support totalitarianism, to lie and betray comrades, or to challenge it to some extent and pay in proportion, by professional losses up to the point of losing work and freedom. The Western scientific community helps to conduct this policy by fully accepting the totalitarian rules of the game in scientific contacts with the USSR and the satellite countries. One example will suffice: did you ever turn back a Soviet delegation because the scientists you had invited were not included [because they were] politically unreliable? Politically reliable people, that is those who help strangle the recalcitrant, are allowed by the Soviet authorities to come out on the international scene. You give your sanction to this selection . . .

"Why not demand, for example, that a small proportion of those who participate in scientific exchange—say, one in ten—must be the other side's choice, and if not, then firmly refuse to cooperate? Scientists hold powerful levers of influence on totalitarian countries. Why do they not use them to save a colleague from imprisonment? . . .

"The detente is necessary, I'm completely for the detente. But in the absence of strong public pressure for human rights all over the world the detente will automatically lead to proliferation of totalitarianism. The Helsinki agreement reveals a typical pattern: the West makes real concessions in exchange for imaginary ones from the East. After Helsinki, the situation with human rights in the USSR has become only worse . . . The proponents of the Helsinki agreement argued that it would provide the grounds for exerting pressure on the USSR for exchange of people and ideas. But what is the use of the grounds if there is no desire to exert pressure? . . ."

## CANADA

## Royal Society may acquire an expanded role

*The ways in which Canada's Royal Society might have a broadened role in the country's scientific affairs is becoming a matter of some controversy. From Ottawa, David Spurgeon reviews the main issues, which focus chiefly on the question of relations with the government.*

THE contract for \$75,000 over a 12-month period which was signed not long ago between the Canadian federal government and the Academy of Sciences of the Royal Society of Canada will enable the academy to undertake a study to identify specific missions in the natural and human sciences that may be of value to the government, and to recommend policies and procedures for carrying them out. Thus, apart from allowing the academy to engage an executive director half-time—he is Donald Hurst, former head of the Atomic Energy Control Board of Canada, the country's regulatory agency in nuclear affairs—the contract may give it a broadened role in Canada's scientific affairs, the implications of which do not delight all its members.

A number of initiatives designed to make the Royal Society more influential in scientific affairs has been taken in recent years. Five years ago, a committee set up by the Society's old Section Three (now the Academy of Sciences) to study how this could be done became a committee of the Society as a whole within months. Now there are three component academies in the Society, the other two being those of the social sciences and humanities (one for the Anglophone section, the other for the French).

One of the reasons some have felt the need of a stronger role for the Royal Society in science was expressed by the geologist J. Tuzo Wilson when he was president in 1973. In an article in *Science Forum* he said that the Society believed that Canada needed "an active and independent academy, not so much to advise government, but to promulgate informed opinions and to lead open discussions of important issues that will aid governments in making their decisions".

Dr Wilson stressed that, unlike the various bodies the government had established for similar purposes, the Royal Society was not a political body. He suggested that its independence, together with its access to leading scientists in many fields, could provide the alternative in scientific advice that

the country needed. It was his view that the whole direction of Canadian science was in the hands of civil servants and members of councils who are appointed by ministers, and he claimed that the whole direction of science had been "politicised".

Not all Society members have agreed on the role the body should take, however. Although some, like Wilson, thought a detached role (in which the Society would make studies in specific areas) was best, others thought it should be closer to the government and play a more official advisory role.

Part of the Society's expanded role may be in international scientific affairs. In other countries, contacts with international scientific unions are usually made through non-governmental bodies, but in Canada the National Research Council has usually provided the point of contact. Some think this anomalous. For the social sciences, the humanities and engineering, Canada has non-governmental organisations that can act as adhering bodies to the international unions: the Social Science Research Council, the Humanities Research Council, and the Canadian Council of Professional Engineers. But there are no corresponding non-governmental bodies for international contact in the medical and natural sciences.

Some members of the Royal Society believe this is a role the Society should play, as academies do in other countries. But the problem of how this could be done remains because of the large number of professional organisations in different disciplines in Canada and the number of constituent bodies of the international scientific unions. One suggestion is that the Society should play the role of clearing house for the appropriate national professional organisations.

A certain amount of scepticism usually accompanies changes which the Royal Society of Canada makes, mainly because many scientists have become accustomed to thinking of the organisation as a self-congratulatory old boys' club. In spite of this, the 'club' counts among its members many of the country's most distinguished scientists (and lately even a few engineers), and it has been stirring itself in recent years to play a more important public role—for example by organising seminars on such topics as the energy problem. The outcome of this latest move will thus be watched with interest. □

## BRITAIN

## University pay grumbles remain

*Last year British university teachers were involved in 'industrial action' before finally resolving their dispute with the government over salary increases. The government has since introduced its pay policy. This month many academics will receive for the first time the cost of living element of their 1975 salaries settlement. David Walker reports on the discontent that still prevails.*

THE Association of University Teachers (AUT), the university authorities and the British government have agreed that the pay code maximum of £6 a week should be added to all academic salaries under £8,500 a year, and the whole package backdated to October. The final figures for the delayed settlement—the basic element was determined by an arbitration body as long ago as May last year—show that junior lecturers have probably benefited most and now start their teaching careers on nearly £3,200 a year. Some staff, who will no doubt bear in mind Mr Healey's recent warning about "confetti money", have increased their annual salaries by £1,000 in the space of 12 months. And one professor of politics told the world on television before Christmas that he was "aggressively satisfied" with his standard of living.

Under the settlement the starting point for all university academic staff, the foot of the lecturer grade, is £3,174 a year rising through 16 incremental points to £6,446. The scale for senior lecturers and readers will now run from £6,234 to £7,742, and the professorial minimum salary will be just below £7,900. Professors outside the clinical subjects will be on an average of over £9,200, although few of them got the £6 a week element or at least got only enough of it to take them to the £8,500 salaries ceiling. The settlement will run for the duration of the Labour government's incomes policy and Mr Laurie Sapper, the general secretary of the AUT, claims they have extracted from the government a firm promise to revise the scales of payment as soon as economic circumstances permit.

In spite of that, there is a lingering mood of dissatisfaction in those senior common rooms where salaries get discussed—and it is a sign of the times that money now gets talked about in public. Those university teachers who take an active part in their trade union (and a key test of their 'militancy' will come in March when they will vote on whether the AUT should affiliate to

the Trades Union Congress, TUC) are still disgruntled. One of the major issues they still consider unresolved is the question of comparisons between their salaries and those paid to polytechnic lecturers and heads of departments.

Straight comparisons between rewards in the two sectors of British higher education are notoriously difficult to make on account of different opportunities for promotion, the numbers of staff, on relative salary points and the balance in teachers' time between teaching and research. Yet they are made, and the AUT officially considers that many university people are comparatively underpaid.

In addition the bi-annual conference of the AUT last December showed that

the government's handling of negotiations on pay during the past year has left a legacy of bitterness. There is talk of "hatred" for the universities in the Department of Education and Science, discrimination in favour of the polytechnics, and—most disturbing—of a Civil Service plot to do down the universities.

The worst of these suspicions are likely to clear in the coming year, however Mr Fred Mulley, the Secretary for Education, is a genial figure who attracts none of the opprobrium heaped on his predecessor, Mr Reg Prentice. Although the university teachers are likely to vote in favour of joining the TUC, it is unlikely that a moderate body like the AUT will do much to steel its arms for militant action on

the issue of salaries.

But action is promised on two fronts that could have important longer term effects on the structure of the profession. The AUT is planning to press for a revision of the ratios of senior to junior staff, on the grounds that there is a serious promotions log-jam, with a great build-up of those on the upper points of the lecturer and senior lecturer scales with little or no prospect of advancement. On another front the AUT is drawing up new salary claims to be presented to the government on the basis of comparison with the Civil Service. This marks an unwelcome development in the eyes of those who fear that the drawing of such analogies will speed the process of bringing universities into full state control. □

FORTY-EIGHT years ago I published the first of a series of papers on the exponential growth of colonies of duckweed and the circumstances under which exponential growth curves became sigmoid. I was following the fashion at that time. Raymond Pearl was doing elegant mathematical analyses of the growth rates of human populations, and Alfred Lotka's brilliant *Elements of Physical Biology* (surely one of the most seminal books on mathematical biology ever written) came into my hands when I was a third year student, just 50 years ago. It is a book which gave, as long ago as that, a masterly treatment of the conditions for equilibrium in biological systems.

So it is with a sensation of nostalgia that I have followed the publications sponsored by the Club of Rome and supervised by Dennis Meadows. It is touching to watch the rediscovery of exponentials, as though Pearl and Lotka had never lived, and ironical to note how much more credible those writers were, working with a slide rule and a little algebra, than Meadows and his colleagues are, armed with a computer. With these thoughts in mind I turned with hope rather than anticipation to the third volume of studies sponsored by the Club of Rome (*Dynamics of Growth in a Finite World*. Pp. 637; Wright Allen; Cambridge, Massachusetts, 1975). Have the authors, as I hoped, at last recognised the fundamental weakness of computer simulations in which the critical parameters—the adaptation of social values and norms to environmental change—have to be omitted because they cannot be quantified?

If this third volume does nothing else, it illustrates the phenomenon of exponential growth. The first volume weighs 170 g and cost \$2.75; the

second weighs 530 g and cost \$18; the third weighs about 900 g and costs (in sterling) the equivalent of \$37. If one makes the assumptions which are the theme of *The Limits to Growth*, the next volume, due in a couple of years,

## Exponentials again

ERIC ASHBY

will weigh 1½ kg and cost about \$60, and the one after that 5 kg, perhaps.

Of course nobody in his senses makes such assumptions, but then neither does he make similar ones about the exponential increase of pollution in nations which have NEPA or the EEC Declaration on the Environment or the Control of Pollution Act; yet a section in chapter six of this book does make precisely this assumption, and the authors reach a conclusion which I think (without immodesty) I could have reached without a computer: "... as long as there is exponential growth in the generation of pollution, ameliorative measures ultimately do little to prevent the model from exhibiting unacceptable levels of pollution

damage" (page 477).

We owe a debt to Meadows and his colleagues for dispelling the utopian mirage: that material standards of living will continue to go up and up, until Indian peasants enjoy the comforts and amenities now enjoyed by the middle classes in Europe. But they do a disservice to their own cause when they imply that their computer simulations can be used as a guide to policy making. A glance at the present state of the world is enough to demonstrate that this naive approach (even though it does include an element of social feedback through the price mechanism) diverts attention from the much higher priorities in policy making. Long before we are starved of resources or smothered in excess population or choked by pollution we are in for a series of grave geopolitical confrontations, to be resolved either by war or by subjection for nations which need resources to conditions imposed by nations which own resources.

The world's future in the short run depends on how these confrontations are handled. The techniques for handling them are not in the hard sciences (though they will buy time) nor in econometrics (which has a dubious record of predictiveness). They are in social anthropology (to understand the nations which may inherit power), in ethology (to understand our own social behaviour under stress), in political science (to help us to devise political systems to match the complexity of post-industrial society). These are the fields which need massive support for research and development. I think sometimes that Britain suffers from a semantic anomaly: that *Wissenschaft* in Germany and *Nauk* in the USSR cover a much wider spectrum of disciplines than our word *Science*.

## Search for organic superconductors

from A. D Yoffe

A THEORETICAL paper published in 1964 by W. A. Little (*Phys. Rev.*, **134A**, 1416) dealt with the possibility of high temperature superconductivity particularly in solids formed from long chain organic molecules. The use of the term "high temperature" is of course a little ambiguous, but a realistic interpretation would put this in the vicinity of liquid nitrogen temperature (77 K) or higher. This theory was based on a particular kind of electron-phonon (vibrational) coupling and it naturally created considerable interest and excitement. First, there were the biological implications and second, there was the vision of a relatively cheap high temperature superconductor for both scientific and industrial use. It should be said that the paper was also greeted with a good deal of criticism and scepticism. This led to a hunt for organic-type solids which would be metals at room temperature and which would remain metals even when cooled to temperatures below that of liquid helium (4 K). This is not an easy problem to solve since pretty well all organic solids are insulators or semiconductors. One exception is of course graphite and the intercalate compounds formed from graphite with, say, alkali metal atoms such as potassium. They are metals in this sense, but they hardly qualify as organic solids.

Crystals of the organic charge transfer complexes such as TTF-TCNQ (tetrathiofulvene - tetracyanoquinodimethane) which are extremely anisotropic in their physical properties, do behave as metals with a conductivity in the region of  $1,000 \text{ ohm}^{-1} \text{ cm}^{-1}$  at room temperature when this is measured along one of the crystal axes. This is the direction along which the molecules are stacked. Further evidence for the metallic nature along this direction came from optical reflectivity experiments using polarised light. When the electric vector of the incident light is parallel to the direction of the stack of molecules (good conductivity direction) then typical metallic free carrier reflectivity is found. When the crystals are cooled below liquid nitrogen temperatures

(round 60 K), however, the electrical conductivity begins to fall, and it seems that the solid changes to a small band gap semiconductor. The solid undergoes what is currently termed a Peierls transition, proposed for one-dimensional metals. In 1973 Heeger and his colleagues at the University of Pennsylvania published some rather startling results on the electrical conductivity for some of their crystals of TTF-TCNQ in which they found the conductivity rose to very high values approaching that for copper, just before the transformation temperature to the semiconducting state. There was talk of superconducting fluctuations and there can be little doubt that these experimental findings created quite a stir and led to the renewed interest in this and similar systems over the past few years.

TTF-TCNQ belongs to the class of solids built up from chain-like structures which are loosely called "one-dimensional conductors". Other examples are  $\text{K}_2\text{Pt}(\text{CN})_4 \cdot \text{Br}_{0.3} \cdot 3\text{H}_2\text{O}$  (commonly abbreviated as KCP(Br)) and the sulphur nitrogen polymer, usually called (SN)<sub>n</sub> polymer. This polymer consists of helical chains of sulphur and nitrogen bound together in the crystal by relatively weak van der Waal's forces. The crystals have the appearance of brass, and in 1975 the IBM group (Greene, Street and Suter, *Phys. Rev. Lett.*, **34**, 577; 1975) reported that crystals of this material did in fact become superconducting, but at a relatively low temperature round 0.3 K. This is the first polymer to be shown to be a superconductor and although the result could be likened to a damp squib when we consider the magnitude of the transition temperature, it is important and provides the hope of synthesising other polymers which have higher superconducting transition temperatures.

Many research groups throughout the world with strong chemical support are at present attempting to synthesise such organic solids which behave as metals at all temperatures and which do not display the unfortunate characteristic of TTF-TCNQ at low temperatures. One interesting development has

been the synthesis of the charge transfer complex HMTSF-TCNQ (hexamethylene tetraselenafulvalinium-tetracyanoquinodimethane) which remains metallic below one degree Kelvin, although it does not become superconducting (Block, *et al.*, *Phys. Rev. Lett.*, **34**, 1561; 1975). Another and rather better example is the organic complex radical anion salt 1,2-di (N-ethyl-4 pyridinium) ethylene<sup>2+</sup> (7,7,8,8 - tetracyanoquinodimethane)<sub>2</sub><sup>-</sup> discussed in this issue of *Nature* (page 201) by Ashwell, Eley and Willis.

A good deal of important physics and chemistry is coming out of this work on solids composed of chains of one kind or another. These crystals are extremely anisotropic in their physical properties, and we find that we are concerned with phenomena such as Peierls distortions, Kohn anomalies, soft phonon modes, superlattice formation, charge density waves and superconductivity. It is clear however that the real goal is the synthesis of organic solids which will become superconducting at reasonable temperatures. The experiments discussed above point the way in which future work might develop. □

### A hundred years ago

THE Ladies' Classes at University College, London, began on Monday last the second term of their eighth session. There was a slight decline in the number of students for the session 1874-75, but the first term of the session 1875-76 showed a considerable advance beyond the highest success hitherto attained. In the Michaelmas term, 1874-75, the whole number of individual students was 199; in the Michaelmas term, 1875-76, just elapsed, the number of individual students was 265. The whole number of tickets taken in Michaelmas term, 1874-75, was 257; in the same term of 1875-76 it was 367. from *Nature*, 13, 235; January 20, 1876

# HeLa takes over

by Sandy Grimwade

ALTHOUGH it was suggested in 1967 by Gartler (*Natn. Cancer Inst. Monogr.*, 26, 167) on the basis of isoenzyme patterns that not all cell lines in common use were what they purported to be, it was not until last year that cytogenetic studies by Nelson-Rees *et al.* (*Science*, 184, 1093; 1974) demonstrated conclusively the extent of contamination. Gartler showed that many commonly used cell lines, supposedly of Caucasian origin, contained the A-type isoenzyme of glucose-6-phosphate dehydrogenase (G6PD), which is in fact found only in approximately 30% of the Negro race. One cell line which legitimately contains G6PD type A is the HeLa line, the oldest and most widely used of all cell cultures, which was established in the early 1950s from the cervical carcinoma of a Negro woman in Baltimore named Henrietta Lacks. The warning attached to that finding was that many cell lines could be contaminated with HeLa.

While identification of a single isoenzyme marker left room for doubt, the advent of chromosome-banding techniques by the trypsin-Giemsa and quinacrine mustard methods showed far more specific markers. Examination of HeLa cell chromosomes by these methods shows four unusual chromosomes formed by fusion of portions of various normal chromosomes. Although there remains some disagreement between various groups of cytogeneticists about exactly which chromosomes have fused to form the markers, there is no divergence concerning the occurrence and appearance of the markers in HeLa cells.

In 1974 Nelson-Rees *et al.* reported that several commonly used cell lines from various human sources contained HeLa marker chromosomes as well as the type A G6PD. A third indication consistent with the claim that these were HeLa cells was that no Y chromosome was present. Several of the cell lines were presumed to be of male origin, and should therefore have shown Y chromosomes, whereas HeLa cells are originally female.

The extent of the HeLa take-over of cell cultures is further documented in this issue of *Nature* (page 211) in a paper from Lavappa, Macy and Shannon from the American Type Culture Collection (ATCC). The ATCC, which preserves cultures of every imaginable microorganism and animal cell, distributes its cell lines to laboratories both in the USA and elsewhere. Several thousand samples of cell cultures are sold on a non-profit basis annually. Shortly after the introduction of the

isoenzyme technique, the screening of the entire stock of human cell lines for type A G6PD was initiated and in the 1972 ATCC Registry of Animal Cell Lines 27 out of 56 lines are flagged as containing this marker isoenzyme. The paper by Lavappa *et al.* presents the first results from a cytogenetic screening programme recently initiated using the newly-available chromosome banding technique. Detailed chromosome analysis of several cell lines reveals that five of the lines, all of which bear the type A G6PD, have HeLa marker chromosomes. Since submission of the paper, several other lines have been tested, and so far all the lines with the suspect G6PD isoenzyme have also been found to bear the HeLa markers. Not all these lines have all four markers, however. Detroit 6 cells, for example, lack HeLa marker (HM) 1, but contain two copies of HM2, 3-4 copies of HM3 and show some variability in HM4. These variations are thought to have arisen by somatic cell hybridisation between the original cell line and contaminating HeLa cells. There is also the remote possibility that these markers have arisen spontaneously in more than one cell line.

The results of the ATCC survey and of several other investigations of cell lines in general use have been combined in an extensive table in a recent *Science* paper by Nelson-Rees and Flandermeyer (*Science*, 191, 96-98; 1976). In addition to the criteria already mentioned, phosphoglucose isomerase and HLA antigen data are included. In all, more than 70 cell lines with HeLa characteristics are listed.

These results should give rise to some reappraisal of results in the many laboratories where these cultures are being used. Investigators who think they are working with liver or bone marrow, for example, may find that they have been dealing with Henrietta Lacks' extraordinary carcinoma all along.

It is interesting to speculate on the reasons for the virulence of HeLa cells and the origins of the widespread contamination. It seems reasonable to say that HeLa cells being the oldest line in existence have been subjected to the maximum selective pressure. HeLa cells have been cultured an untold number of times. Those in the ATCC have probably been passaged more than 400 times since their initial isolation in the relatively unrefined culture conditions of 1951 and are therefore perfectly adapted to laboratory conditions. The chromosome studies at the

ATCC were carried out on cells passaged only once or twice from the frozen seed stock. As the cell lines now shown to be contaminated with HeLa were mostly frozen and deposited at the ATCC in the early 1960s, often after several hundred passages, the contaminations probably occurred long before their deposition at the ATCC in laboratories where more than one cell line was being handled. The basic biochemical or genetic reason for the virulence of the HeLa cells which would account for their ability to take over any cell culture remains a mystery however.

Although several of its human cell lines are now shown to be contaminated with HeLa, and up to half of them are suspect, the ATCC intends to continue carrying these lines in its catalogues. Despite the fact that the cell lines are similar in their chromosomes, they retain individual characteristics, such as growth rate and virus susceptibility, worth preserving. □

## Nova Cygni 1975

from P. J. Andrews

NOVA Cygni 1975, first reported by Honda, was independently discovered by hundreds of astronomers as a bright star in the constellation Cygnus on the evening of August 29. It subsequently became the brightest nova seen since Nova Puppis 1942. First indications that the nova was unusual came when a search for the prenova on the Palomar Sky Survey plates showed no star at the nova's position. The rise in brightness, 18 mag, was greater than any previously known; in fact it led to the suggestion, subsequently refuted, that the object was a supernova.

The most widely held theory for the nova phenomenon is that the prenova is a close binary system consisting of a red dwarf, which is filling its Roche Lobe, spilling matter over towards a white dwarf companion. The period of the binary is shorter for systems containing fainter, cooler red dwarfs. The nova outburst is believed to be due to the flow of material from the red star passing by way of an accretion disk to the white dwarf's atmosphere where it is compressed and heated by the gravitational field until it reaches the ignition temperature for hydrogen burning reactions. Once ignition occurs there is a thermonuclear runaway generating the necessary energy to produce the very hot expanding shell of gas which is seen as the nova eruption.

The development of the nova is the evolution of this expanding region. In general the development is complex with several different systems of absorp-

tion lines present in the spectrum which are due to gas ejection continuing after light maximum. For some novae there are great changes in this outflow which are manifested in dramatic changes in the light curve and spectrum.

Nova Cygni, being bright and easily accessible to all northern observatories, was expected to throw light on the various rival theories for different aspects of the nova phenomenon. Unfortunately it does not seem to be, in any sense, a typical nova.

From comparison of the strengths of the interstellar lines in the early spectrum of the nova with those in the supergiant 55 Cygni, Tomkin, Woodman and Lambert (*Astron. Astrophys.*, in the press) deduced a distance for the nova of somewhat greater than 1 kpc and an intrinsic visual luminosity at maximum of about  $-10$  mag. A similar brightness was obtained from the rate of decline in brightness shortly after maximum by Lindgren and Lindgren (*Nature*, **258**, 501, 1975). This intrinsic luminosity is the highest known for a galactic nova, and the speed of decline is the fastest.

The spectrum during this rapid decline also changes very rapidly and does not show all the 'normal' absorption systems seen in typical novae spectra. Possibly this indicates that for Nova Cygni an instantaneous ejection model is more applicable than the continued ejection models which seem better suited to most novae.

While the decline from maximum light has, compared with many novae, been remarkably smooth, the confirmation (Mancocci, Messi, Natali and Rossi, page 186 of this issue of *Nature*) of a small periodic variation in brightness with a period of some 3 h suggests the possibility that some form of modulation of the nova's brightness is being caused by the orbital motion of the binary.

The observation of coronal lines in the near infrared by Grasdaen and Joyce (see page 187) indicates the presence of a very high temperature ( $\sim 10^6$  K) region where apparently the degree of ionisation is still increasing. They suggest that there is the possibility of determining the physical conditions and abundances in this region which is presumably situated close to the site of the nova explosion. Abundance determination should also be possible for a series of high dispersion spectra obtained at the Royal Greenwich Observatory by Stickland within 8 h of discovery. A preliminary analysis by the author indicates that the strengths of the CII, OII and especially NII lines are greater than would be expected suggesting that these elements have greater than normal abundance. This would agree with the theoretical pre-

dictions of Starrfield, *et al.* (*Astrophys. J.*, **176**, 169; 1972) who indicated that these elements will be enhanced in this way by the nova mechanism discussed above.

Shortly after maximum light the spectrum became dominated by emission lines which became progressively stronger relative to the continuum as the nebular stage was approached. At the same time structure at the top of each emission line became apparent. Thus structure, initially seen as four peaks at each emission line, has subsequently developed so that by the end of September up to eleven peaks were seen and measured in each of several different spectral lines. The derived velocities were constant for each peak, where present, for all the spectral lines measured. The expanding nebula is thus strongly lobed in a very complex manner which together with observations of circular polarisation in H $\alpha$  and H $\beta$  by Kemp and Rudy (*IAU Circ.* 2837) perhaps supports Mustel's ideas that strong magnetic fields are present in novae.

There is, no doubt, an enormous amount of observational data on Nova Cygni accumulating. The first results are only now starting to appear, but Nova Cygni seems so far to have posed more problems than it has solved.  $\square$

## Expression of eukaryotic genes in prokaryotes

from Giorgio Bernardi

MANY of the hopes, and some of the fears, associated with future developments in the field of genetic engineering rely upon the possibility of transcribing and translating eukaryotic genes in prokaryotic systems. It is not yet clear, however, whether the ambitious goal of converting bacteria into factories for the synthesis of medically, agriculturally and industrially important proteins of eukaryotic origin can be achieved without some additional advances in our technology.

Following the pioneering work of Berg and his colleagues at Stanford, restriction endonuclease-generated DNA fragments from various sources have been cloned in *E. coli* by linking them to a plasmid (or a phage) replicon, and then introducing the composite molecules into bacterial cells by transformation. After having been first used to introduce segments of other bacterial plasmids and phage DNA into bacteria (see for example Chang and Cohen, *Proc. natn. Acad. Sci. U.S.A.*,

**71**, 1030; 1974; Hershfield *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **71**, 3455; 1974; Tanaka and Weisblum, *J. Bact.*, **121**, 354; 1975), this method has been used to clone fragments of eukaryotic DNA, such as *Xenopus laevis* amplified rDNA (Morrow *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **71**, 1743; 1974), *Drosophila melanogaster* DNA (Wensink *et al.*, *Cell*, **3**, 315; 1974; Thomas *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **71**, 4579; 1974; Glover *et al.*, *Cell*, **5**, 149; 1975; Tanaka *et al.*, *Biochemistry*, **14**, 2064; 1975) and sea urchin histone genes (Kedes *et al.*, *Nature*, **225**, 535; 1975; Birnstiel *et al.*, *Xth FEBS Meeting*, **38**, 3; 1975).

In order to study the expression of eukaryotic genes in the prokaryotic host, advantage has been taken of the fact that plasmids segregating into minicells (which are devoid of bacterial chromosomal DNA) are capable of plasmid-specific synthesis of functional gene products (Frazer and Curtiss, *J. Bact.*, **115**, 615; 1973; Van Embden and Cohen, *J. Bact.*, **116**, 699; 1973). For both rDNA and histone genes, it has been shown (Morrow *et al.*, *op. cit.*; Kedes *et al.*, *op. cit.*) that transcription takes place in minicells; the fidelity of transcription has not, however, been demonstrated in either case.

A novel approach to this problem has been tried by Chang, Lansman, Clayton and Cohen (*Cell*, **6**, 231; 1975) by looking at the expression of mouse mitochondrial DNA in minicells. This genome has a size of only  $10 \times 10^6$  and can be cloned in its totality, thus providing an opportunity for studying transcription and translation of a complete eukaryotic genome in a prokaryotic system, in contrast to previous studies which only involved genome fragments.

Covalently closed, circular mtDNA was partially digested with *EcoRI* restriction endonuclease, (in order to obtain linear molecules broken at only one of the two *EcoRI* sites on mouse mtDNA), and annealed with *EcoRI*-digested pSC101 plasmid DNA; after ligation, the DNA mixture was used to transform *E. coli* cells which were grown in the presence of tetracycline, to allow selection of cells transformed by the antibiotic resistance-carrying plasmid. The total closed, circular DNA population was then isolated from transformed cells and fractionated by sucrose gradient centrifugation. The 44S DNA molecules, corresponding to a molecular weight of  $16 \times 10^6$ , and therefore to the sum of mtDNA plus plasmid DNA, were amplified by a second cycle of transformation. Four different chimaeric molecules were recognised by heteroduplex analysis and by degradation with *HindIII*, a restriction enzyme having three sites on mtDNA and one (practically coinci-

dent with the *EcoRI* site) on pSC101. These molecules differed in the mtDNA *EcoRI* site used for plasmid insertion and in the relative orientation of plasmid and mtDNA.

MtDNA was then isolated from *EcoRI* digests of chimaeric plasmids by centrifugation in CsCl-netropsin density gradients, and separated into its heavy and light strand by centrifugation in alkaline CsCl. RNA labelled for 30 min with <sup>3</sup>H-uridine, obtained from minicells carrying chimaeric plasmids showed a continuous size distribution, as if unstable messenger-like RNA was being isolated in different stages of synthesis and degradation. In addition, most of the 30 min- and 3 min-labelled RNA hybridised to the L-strand, whereas little, if any, hybridised to the H-strand. Since the preferential transcription of the L-strand is not influenced by the relative orientation of pSC101 and mtDNA in the chimaeric molecules, it is improbable that transcription of the L-strand depended on a pSC101 promoter and read through at the mtDNA-pSC101 junction. Thus, one or more signals located within the L-strand are, indeed, recognised by the *E. coli* RNA polymerase. This does not, however, establish any structural identity between these sites and the promoter regions used inside functional mitochondria. In fact, as stressed by the authors, the opposite view is favoured by two lines of evidence. *In vivo*, mitochondrial rRNAs and most tRNAs and mRNAs are transcribed from the H-strand, only three tRNAs and one mRNA originating from the L-strand (Attardi *et al.*, in *The Biogenesis of Mitochondria*, 9, edit. by Kroon and Saccone, Academic Press, 1974). *In vitro*, mitochondrial RNA polymerase preferentially transcribes the H-strand (Wu and Dawid, *J. biol. Chem.*, **249**, 4412; 1974), whereas *E. coli* RNA polymerase preferentially transcribes the L-strand (Tabak and Borst, *Biochim. biophys. Acta* **217**, 356; 1970; Dawid, *Devl Biol.*, **29**, 139; 1972).

The total incorporation of <sup>3</sup>H-leucine into protein in minicells carrying the four types of chimaeric plasmids was found to be 2-4 times higher than that obtained from minicells containing pSC101 alone. The label was present in four polypeptides ranging in molecular weight from 2,500 to 5,000; four of the five pSC101-determined proteins were also seen. The protein synthetic pattern observed suggests that translation occurred from RNA transcripts of mtDNA; it differed, however, from that observed in mouse mitochondria, in which case seven proteins ranging in molecular weight from >40,000 to <10,000 were detected.

Among the additional findings of Chang *et al.*, one is of particular

interest, namely that the mtDNA origin of replication is not used at a significant frequency in chimaeric plasmids. In fact, all the *EcoRI* fragments originating from them and having the electron microscopic appearance of replicative intermediates had the length of pSC101; furthermore, their replication origins mapped in positions known to be the pSC101 replication origin.

To sum up this remarkable work, it has been demonstrated for the first time that transcription of eukaryotic DNA in prokaryotes can actually start at signals located on the eukaryotic DNA itself instead of being the result of read through from the plasmid; such transcripts, which appear to be translated in minicells, do not seem, however, to start at natural promoter sites on mtDNA and, therefore, do not correspond to any of the natural transcripts of the mitochondrial genome. This conclusion, which may, perhaps, disappoint the proponents of the prokaryotic origin of mitochondria, suggests that only a mitochondrial RNA polymerase is able to recognise mitochondrial promoters. In this case, the successful expression of eukaryotic genes in prokaryotes may need selective resection of their control elements, which should be replaced by those of plasmid or phage vectors (Murray *et al.*, *Xth FEBS Meeting*, **38**, 193; 1975). It should be recalled, however, that most of the mitochondrial transcripts are, in fact, derived from the processing of the single RNA copy of the H-strand (Aloni and Attardi, *J. molec. Biol.*, **70**, 363, 1972). Such a situation, implying the presence of a single promoter on the H-strand, makes animal mtDNA an unfavourable model to test its faithful transcription in minicells and leaves the door open, for the time being, to some optimism over the possibility of correct expression of eukaryotic genes in prokaryotes. An encouraging result along this line is the very recent finding by K. Struhl, J. Cameron and R. Davis of Stanford University of complementation of a *E. coli* *hisB* mutation by a yeast DNA fragment inserted into  $\lambda$  DNA. □

## B chromosomes in grasshoppers

from John Bishop

B CHROMOSOMES are chromosomes which appear in some but not in other members of a species, and as such are clearly not necessary for the survival of

individuals. The designation B indicates a supernumerary chromosome, in contrast to the A chromosomes, the representatives of the normal complement.

B chromosomes occur in many species of animals and plants. They are heterochromatic, do not pair with A chromosomes, and have no simple Mendelian effects upon the phenotype. They have been observed, however, to have very sharp clinal distributions which suggest a greater tolerance of B chromosomes under more favourable environmental conditions. The evolutionary significance of B chromosomes is elegantly explored in a paper by Hewitt in *Chromosomes Today* (4, edit. by Wahrman and Lewis, Wiley, New York, 1972).

Several studies have pointed to homologies between different B chromosomes and autosomes, centric fragments and X chromosomes. This suggests the exciting possibility that B chromosomes might represent one of the routes by which the genomes of eukaryotes change radically in informational content to take advantage of changing environmental opportunities. The B chromosome, being heterochromatic and therefore at least largely inactive, would be freed from selective constraint; but could be called on again (perhaps randomly) when and if it fulfilled a newly required function.

Because of this, it was both surprising and disquieting when Gibson and Hewitt (*Nature*, **225**, 67; 1970; *Chromosoma*, **38**, 121; 1972) suggested that the incidence of B chromosomes in the grasshopper *Myrmeleotettix maculatus* was correlated with the occurrence of a DNA satellite which accounted for as much DNA as the B chromosome(s) could be expected to comprise, if not more.

A satellite DNA is one with a different base composition and therefore a distinct buoyant density from the bulk of the DNA (the main-band DNA). Characteristically, a satellite DNA consists of very many similar short sequences (less than 20 nucleotide pairs) arranged tandemly in long continuous stretches (greater than 30,000 nucleotide pairs). On the other hand main-band DNA is largely composed of non-repetitive sequences intimately interspersed with repetitive sequences that have a much lower repetition frequency than satellite DNA.

If B chromosomes contained DNA that had such a degree of disparity with the A chromosome DNA then it would seem unlikely that the two were in any way related. This would very much weigh against the idea that B chromosomes are in the mainstream of the generation of new genetic function. If this were general, it would close, in eukaryotes, an enticing door which has only more recently

In liquid crystals long molecules are aligned parallel to one another but are disordered and free to move in the plane perpendicular to their long axis. The ends of the molecules may all be in register (smectic) or not (nematic), with all the chains parallel, or in register with successive layers of molecules tilted in different directions (cholesteric). It has always seemed likely that some synthetic polymers might form liquid crystals but until recently there has been no example of this in a pure polymer. Liquid crystal formers have a characteristic melting behaviour. On heating there is a change from crystal to liquid crystal with a large heat of transition followed a few degrees later by a transition with a small heat to the liquid. One should also be able to observe the partial ordering by X-ray diffraction and the molecular motion in the liquid crystalline phase by NMR.

Beatty and co-workers at Xerox (*Macromolecules*, **8**, 547; 1975) have now described an almost perfect example of such melting behaviour in polydiethylsiloxane. Calorimetry and X-ray diffraction provide supporting evidence and restricted molecular motion was observed by NMR and dielectric measurements. In other respects polydiethylsiloxane is a normally behaved semi-crystalline polymer and the amorphous regions of the structure seem unaffected by

the transition in the crystalline parts. Polysiloxane chains are quite flexible although it would seem more reasonable to expect liquid crystalline phases in stiff chains, where the inter-chain bonding could loosen at lower temperatures than those at which the chains could become free to rotate internally.

The morphology of the liquid crystalline phase and the mechanism of the transition from liquid to liquid

## Polymeric liquid crystals

from Paul Calvert

crystal and from liquid crystal to crystal in terms of chain folding and spherulite formation have yet to be elucidated. The work of Price and Stein (*J. Phys. Chem.*, **77**, 396, 399, 409; 1973) on the crystallisation kinetics of cholesteric liquid crystals provides a starting point for considering what is expected in the polymeric system.

It is possible that other polymer liquid crystalline phases have been overlooked because of their narrow temperature range. Beatty mentions a series of atactic stiff chain acrylates which have similar X-ray diffraction and melting behaviour to liquid crystals. These materials, however,

do not form true crystals and probably fit better into the grey area between ordered glasses and disordered crystals. A better example is the phase observed to form at high pressures in polyethylene by Bassett (*J. appl. Phys.*, **45**, 4146; 1974). This shows the same behaviour as polydiethylsiloxane though Bassett favours a disordered hexagonal crystal phase at present. He suggests that this phase is the cause of extended chain (large) crystal formation in polyethylene at high pressures. If this is a liquid crystal phase one could expect that extended chain crystals will also grow from polydiethylsiloxane.

There are some examples of solutions of polymers which form liquid crystals. Stiff chain aromatic polyamides in solution in acids form liquid crystals at about 10% polymer. Poly- $\gamma$ -benzyl-L-glutamate in dichloromethane is similar (Duke and DuPré, *Macromolecules*, **7**, 374; 1974; Hines and Samutski, *Macromolecules*, **6**, 793; 1973), on the face of it, however, these solution systems are a different case from pure polymer.

This would be a good time for polymer physicists to predict the arrangement of chains in the liquid crystalline phase and to predict which other polymers should form liquid crystals. Current theories of polymer crystallisation seem rather *ad hoc* and a successful prediction could add respectability.

been opened towards the prokaryotes (Wallace and Morowitz, *Chromosoma*, **40**, 121; 1973).

The situation reported for *M. maculatus* was not, however, observed in other organisms (see for example Chilton and McCarthy, *Genetics*, **74**, 605; 1973). Furthermore, the *M. maculatus* satellite had most unusual properties: not only did it contain highly-repetitive DNA, as do all DNA satellites, but most of it consisted of DNA sequences which, as far as the satellite was concerned, were unique. This was, so to speak, a unique observation.

From the same group in Norwich, but with different authorship, there came recently a confirmation of the correlation between B chromosome content and the occurrence of satellite in *M. maculatus* (Wilmore and Brown, *Chromosoma*, **51**, 337; 1975). This study pointed up a most interesting coincidence: the buoyant density of the *M. maculatus* satellite is identical to that of *Paramecium aurelia* DNA, to the third decimal place. It also has much the same analytical complexity (compare Gibson and Hewitt, *Chromosoma*, **38**, 121; 1972; and Cummings, *Chromosoma*, **53**, 192; 1975).

Yet more recently, Dover and Henderson (*Nature*, **259**, 57; 1975) have reopened the issue by examining some of the same populations of *M. maculatus* previously examined by Gibson and Hewitt. They did indeed find B chromosomes, but found no satellite, even in the presence of actinomycin D. In fact, grasshoppers as a group seem to be unusually free of satellites (Wilmore and Brown, *op. cit.*, 1975).

The unusual properties of the satellite observed by Gibson and Hewitt offer a conceivable solution to the problem. It shows the characteristics of an entire genome, rather than those common to other eukaryotic satellites, and furthermore, it is uncannily like a ciliate genome. It seems possible, then, that the DNA of some grasshoppers is contaminated by that of a ciliate, perhaps a ciliate parasite. It is not by any means inconceivable that the distribution of such a parasite would correlate, perhaps loosely, with that of B chromosomes.

Whatever the eventual explanation it would seem that B chromosomes may soon return securely to their former place as potential progenitors of genetic diversity in eukaryotes. Perhaps this

is one instance in which a negative finding could ultimately outweigh a positive one. □

## The early Earth

from Lynn Margulis

The second College Park Symposium—Chemical Evolution in the Precambrian—was held at the University of Maryland on October 29–November 1. It was sponsored by NASA and the NSF and organised and chaired by Professor Cyril Ponnamperna, Laboratory of Chemical Evolution, Department of Chemistry, University of Maryland. The proceedings will be published by Academic Press, New York, jointly with last year's College Park Symposium on the giant planets.

WHAT were conditions like 4 thousand million years ago? Despite enormous diversity in training, formal back-

ground, methods and scientific approaches amongst the participants agreement on certain basic concepts did emerge at the meeting. V. Rama-Murthy's (University of Minnesota) description of the role of the iron-nickel-lighter substances in the formation of Earth's core and G. Wetherill's (Carnegie Institution of Washington) time scale and planetological-geological framework for the early Precambrian seemed generally accepted. The early planetary period began about 4.43 billion ( $10^9$ ) years ago (bya) when heavy bombardment of the Earth by Solar System debris occurred and is thought to have gone on until about 3.88 bya. From this time until the present we have at least an intermittent but continuous rock record. A middle period of meteoritic bombardment is recognised between 2.85 and 2.6 bya which corresponds to the principal period of igneous activity on the Moon and is thought to have also been marked by volcanism on the Earth. These events "reset" most of the older geochronological clocks. Challenging previous work by Goldich claiming an age of 3.8 byr, Wetherill and his colleagues claim that the Earth's most ancient rocks reliably aged to date have been found on the coast of Labrador and in Greenland. These old gneisses were probably contiguous some 3.62 bya. Only slightly younger than the oldest rocks themselves is the oldest evidence for life in sediments. J. Henderson (Geological Survey of Canada) described sialic crustal material from the Archaean above a granitic basement about 3.0 byr old (Slave Structural Province, Canada). The oldest presumptive evidence for life here is based on black carbonaceous shales and those laminated heros of the Precambrian stage—stromatolites. Thus, Canada is beginning to compete for attention with the remarkable ancient sediments of the lower Precambrian in southern Africa's Swaziland System.

Whereas the Isua Series (the ancient rocks of southwestern Greenland) of moderately metamorphosed sediments yield a rather dull carbon profile with none of the finely dispersed kerogen-like materials typical of younger rocks, only traces of methane and so forth and rather lunar-like with respect to paucity of carbon, the South African (Swaziland Supergroup) Onverwacht and Fig Tree sediments are much richer. B. Nagy (University of Arizona) and his colleagues found aromatic hydrocarbons (by ozonolysis) and, in the Fig Tree, long chain normal alkanes as well. In the organo-geochemical analyses of the Transvaal stromatolite kerogen considerably more hydrocarbon, oxygen, nitrogen and sulphur compounds are found in the

sediments (2.3 byr). Of course interpretations are risky but it is highly possible that life arose between 3.6 and 3.0 bya and that for a while both chemical and biological evolution continued together. (The possibility that the Fig Tree microspheres are not biological but rather prebiotic chemical fossils was well explored by J. Wm. Schopf (University of California, Los Angeles).)

Although alternative interpretations are possible it seemed that the participants at the meeting would tend to endorse the following scheme. Shortly after the Earth stabilised life evolved and went into Darwinian motion and by 2.7 bya (in Canada and South Africa) bacteria and blue green alga had evolved, diversified, and were flourishing as demonstrated by L. A. Nagy's (University of Arizona) Transvaal microfossils (2.3 byr old) of both coccoid and filamentous forms.

For the history of the atmosphere both J. C. G. Walker (National Radio Observatory, Arecibo, Puerto Rico) and R. Siever (Harvard University) presented arguments that degassing from the interior of the Earth probably occurred during the earliest accretion phase (4.55–4.33 bya) and that most other gaseous emission since then has been recycling rather than accumulating. Everyone seemed to agree with Siever that the earliest Archaean atmosphere was anoxygenic but that in other ways (with respect to weathering, composition and total pressures) the atmospheric-surface processes were not very different from those today. Neither Siever nor Walker (nor anyone else) argued that the Archaean atmosphere containing hydrogen, methane and ammonia was highly reducing. Nor did that seem to bother anyone. For example, C. Folsome (University of Hawaii) demonstrated that he could make perfectly good organic microspheres in Urey-Miller type electrical discharges with  $\text{CO}$ ,  $\text{CO}_2$  and  $\text{N}_2$ . In this system, although methane could replace  $\text{CO}_2$  as a carbon source, it was not required for the abiotic generation of simple organic "formed bodies". There was agreement with P. E. Cloud Jr's concept that the atmospheric transition from anoxygenic to oxygenic occurred some 2 bya. A common surface mat blue green alga (for example *Lyngbya* sp.) survives potentially lethal quantities of ultraviolet for days when afforded protection by "matting" (inoculum size) and/or sodium nitrate or nitrite in the medium (Rambler, Boston University) so it is likely that even before the appearance of stratospheric ozone, algal mat communities could cope with ultraviolet light.

T. Hoering (Carnegie Institution of Washington) inspired a good deal of

enthusiasm with his preliminary data on hydrogen isotope fractionations found in fossils and presumably generated biologically. Whatever the real cause of these fractionations, deuterium/hydrogen ratios promise to serve us well as a complement to carbon isotope work.

Although everyone agreed that the Precambrian was the "age of the prokaryotes" there was no consensus concerning the time of first appearance of eukaryotic cells. Primary sequence data on primitive proteins such as ferredoxin (D. O. Hall, Kings College, London) and cytochromes (Cohen and M. Dayhoff, Georgetown University) are proving helpful in reconstructing the evolutionary past. Extrapolations from accepted point mutation rates in proteins and RNAs do suggest that Schopf's evidence for the appearance of nucleated algae by the time Bitter Springs deposits were made ( $850 \pm 100$  Myr) is very reasonable.

But that rich fossil assemblage may indeed be evidence not for eukaryotes but for the acme of prokaryotic development. Schopf led a lively discussion in which he maintained that "nucleated organisms were extant prior to  $850 \pm 100$  Myr and that the lineage may well have been established as early as  $1,400 \pm 100$  Myr ago." Some of our results with artificial "fossils" (using ethyl silicate) and Knoll and Barghoorn's observations on partially degraded blue green algae counsel caution in interpreting the Bitter Springs fossil biota as containing *bona fide* remains of chlorophyte or rhodophyte algae.

The Proterozoic (2 bya) Gunflint stromatolites and microfossils were discussed excitedly in terms of their modern counterparts. *Metallogenium* (a manganese and iron-oxidising microbe discovered by the Russians) bears a striking resemblance to the Gunflint genus *Eoastirion* (E. S. Barghoorn, Harvard University). Everyone welcomed B. Siegel's (University of Hawaii) presentation on newly collected cultures of the enigmatic *Kakabekia barghoorniana*, the microbe that so resembles the Gunflint fossil *Kakabekia umbellata*. Although new data is available on this organism, which has now been collected from diatom-rich cold alkaline places all over the world, the details of its life cycle and culture requirements remain unknown.

Attacking the site of the origin of life itself straight on L. Onsager (University of Florida, Miami) discussed interfacial polymerisation processes that might have occurred at the geochemically derived "primordial oil slick", which, theoretically at least, was conveniently supplied by M. J. Dwyer (University of Philadelphia).

*There is mounting evidence that past extinctions of faunal species have occurred in near coincidence with reversals in polarity of the geomagnetic field. Could the link lie in catastrophic depletions of stratospheric ozone caused by solar-proton irradiation over a reduced geomagnetic field?*

We discuss here a new mechanism that could explain the apparent correlation between faunal extinctions and reversals of the geomagnetic field more satisfactorily than other mechanisms proposed so far.

Uffen has suggested<sup>1</sup> that the surface of the Earth could be exposed to abnormally high fluxes of radiation during the periods of reversal of the polarity of the geomagnetic field (see ref. 2). During these geologically brief periods, the shielding effects of the magnetic field would be removed, or at least severely weakened, allowing galactic cosmic rays to have access to the entire Earth, instead of merely to high-latitude regions, and also causing the radiation belts to precipitate. Uffen proposed<sup>1</sup> that this enhanced level of radiation could lead to increased mutation rates among living species, thereby explaining sudden appearances and disappearances of species from the palaeontological record.

His suggestion has since been examined<sup>3,4</sup> and it is now generally felt that the effect on living species would probably be insignificant. Nonetheless, there is mounting evidence that a correlation does exist between major faunal extinction and geomagnetic polarity reversals. The validity of this correlation in fairly recent geological time seems to have been well established by studies of fossil species of radiolaria (single-celled, marine microorganisms). Using deep-sea cores obtained from a variety of locations, Hays<sup>5</sup> has determined that during the past 2.5 Myr eight species became extinct, and that six of those disappeared in near coincidence with polarity reversals.

Hays has estimated that the probability of a chance coincidence between faunal extinctions and polarity reversals is less than 0.002 (see also refs 6 and 7). Going back still further in time, there is more tenuous evidence of a general correlation between polarity reversals and extinctions of both marine and terrestrial fauna<sup>8,9</sup>. The establishment of a clear case for the radiolarian extinctions has only been possible through a fortunate combination of circumstances that allows the distinctive fossilised siliceous skeletons of the radiolaria to be studied in direct relationship to the geomagnetic record in the same deep-sea cores.

Hays' work<sup>5,7</sup> has shown that individual species can survive through several polarity reversals, though they may often

decrease in numbers at the time of a reversal, before finally disappearing. This suggests that the harmful effects accompanying a polarity reversal, whatever they may be, form only one component of the total environmental stress on a given species. Extinction may result from the addition of this factor to others that are already subjecting the species to severe stress at the time of the reversal.

Other mechanisms linking changes in the geomagnetic field with effects on living organisms have been proposed, include climate changes<sup>10</sup> and direct magnetic effects on growth<sup>5,9</sup>, among others. None has yet received acceptance, however.

Many solar flares generate fluxes of energetic particles, mostly protons, at the Earth. These events occur sporadically, though their frequency of occurrence is strongly dependent on the general level of solar activity manifested in the 11-yr solar cycle. The energies of the individual particles cover a very wide range, from roughly 10<sup>4</sup> eV to over 10<sup>9</sup> eV, and the intensities and spectra are extremely variable from event to event. Though the fluxes of particles capable of reaching the lower atmosphere or ground level (that is, those with energies in excess of 10<sup>9</sup> eV) are generally small and of short duration, however, very substantial fluxes, often persisting for many days, reach the stratosphere during many events.

Crutzen *et al.*<sup>11</sup> have shown that the ionisation produced in the stratosphere by these particles leads to the formation of nitric oxide in large quantities through the dissociation and the dissociative ionisation of N<sub>2</sub>, followed by the reaction of N atoms with oxygen. A few intense events a year can produce NO in amounts comparable with those produced by the main known source (the oxidation of N<sub>2</sub>O), and considerably larger than those produced by galactic cosmic rays. Ozone is catalytically destroyed by NO (ref. 12) chiefly through the pair of reactions

thus directly affecting the efficiency of the ozone shield that protects the surface of the Earth from potentially harmful solar ultraviolet radiation. Although each solar-proton event lasts only a few days, the lifetime of NO in the stratosphere is long, and its effect on the ozone layer is likely to persist for several years.

At present, the geomagnetic field effectively guides the solar protons towards high geomagnetic latitudes, and for most practical purposes the direct effects on the atmosphere are confined to geomagnetic latitudes higher than about 60°. The long lifetime of NO ensures that it will be spread over the Earth by horizontal transport, but it will be diluted by a geometrical

\*On leave from the Institute of Geophysics, University of Oslo.

Fig. 1 An approximate estimate of the fraction of the global stratospheric surface exposed to solar protons of 30 MeV energy as the Earth's dipole moment,  $M$ , is changed from its present value  $M_0$ .

factor of about 7, corresponding to the fraction of the Earth lying at latitudes higher than  $60^\circ$ . During polarity reversals, however, the dipole component of the geomagnetic field probably weakens or disappears for periods of a few thousand years<sup>13</sup>, allowing both solar protons and galactic cosmic rays access to much larger areas of the Earth, and leading to much more severe effects on the ozone shield than are possible at present. Biological species that had evolved over the preceding several million years of geomagnetic stability may be unable to survive the harsher ultraviolet environment, and would presumably be replaced by other species with more adaptability. It is worth noting that many contemporary simple forms of aquatic life seem to be intolerant of enhanced ultraviolet radiation in the 300-nm wavelength range<sup>14</sup>, which can penetrate water to depths of several metres<sup>15</sup>.

This mechanism is related to one proposed by Ruderman<sup>16</sup>, who suggested that the sporadic occurrence of supernovae in the past might have subjected the Earth to intense fluxes of radiation, resulting in a removal of the ozone shield through the catalytic action of NO. This mechanism should certainly be considered, but it cannot explain the observed correlation between major faunal extinctions and polarity reversals. The solar-proton hypothesis, on the other hand, provides at least a tentative explanation of this mysterious relationship.

Fig. 2 Fractional depletion of the total content of the ozone column of the stratosphere produced by intense solar-proton events in the absence of a geomagnetic field. The events are assumed to have the same spectrum as that of the August 1972 event, and the abscissa indicates the particle flux in units of the August 1972 flux. GCR, the calculated depletion produced by the continuous action of galactic cosmic rays.

Besides undergoing polarity reversals, the intensity of the geomagnetic field varies on a time scale of thousands of years. There is no evidence for any biological effects related to this variation, and a possible explanation is illustrated in Fig. 1. This shows the fraction of the global atmospheric surface accessible to protons of 30 MeV energy as a function of the geomagnetic dipole moment, normalised to unity at its present value. Since 30 MeV is roughly the minimum energy needed to reach the stratosphere, this quantity represents the fraction of the stratosphere that is exposed to the full available solar-proton flux. The calculation is approximate, based on a simple dipole field, in which the Störmer theory of geomagnetic cutoffs is applicable, with a  $5^\circ$  correction applied to take account of the distortion of the outer regions of the field by the solar wind<sup>17</sup>. Figure 1 shows that the dipole moment must be reduced by a factor of 10 or more before the area directly affected by solar protons is greatly increased. Evidence from rock magnetisation studies indicate that the field intensity does decrease by an order of magnitude during polarity reversals, but that it does not completely disappear. The remaining field is likely to comprise

Fig. 3 *a*, Calculated ozone height profile for normal conditions, *b*, fractional depletion produced by solar-proton events of the indicated magnitudes (relative to the event of August 1972), and by galactic cosmic rays (GCR).

mainly non-dipole components whose effect on energetic particles is impossible to estimate. It is likely, however, that non-dipole fields will allow freer access than would dipole fields of similar strength. We assume here that the field actually disappears during polarity reversals.

Solar-proton events have been studied only during the past 15–20 yr. Based on the accumulated evidence, it is difficult to estimate the maximum intensity that an event may reach during an episode of polarity reversal lasting perhaps a thousand years or more. The most intense event known was that of August 1972, during which about  $2.5 \times 10^6$  erg  $\text{cm}^{-2}$  entered the high-latitude atmosphere in the form of protons with energies greater than 30 MeV, which penetrate into the stratosphere. It does not seem that events one or two orders of magnitude more intense than that of August 1972 can be ruled out when the observation period is lengthened to more than 1,000 yr. The quantity of NO that can be produced during extremely intense events is not unlimited, however, since the reaction

which re-creates  $\text{N}_2$  from dissociated N atoms, assumes major importance when the NO concentration is high.

Figure 2 shows our estimate of ozone reductions resulting from the increased stratospheric production of NO by the continuous action of galactic cosmic rays and by sporadic solar-proton events occurring during polarity reversals. It is assumed that during these periods the atmosphere is otherwise unchanged from its present state. The calculations were carried out using a one-dimensional, time-dependent, photochemical model, which is an extension of a model developed by one of us (P.J.C.), and which will be described elsewhere. The production rates

of NO from galactic cosmic rays were obtained from a study by Brasseur and Nicolet<sup>18</sup>. The magnitudes of the solar-proton events are here measured in terms of the August 1972 event, but it must be remembered that in reality different events differ greatly in their particle energy spectra as well as their fluxes. The numbers probably represent underestimates of the effects, since the conditions of the model calculations were chosen to simulate the effects of the solar protons at low latitudes. As NO production from the oxidation of N<sub>2</sub>O is a maximum at low latitudes, the contribution of NO from solar-proton events relative to that from N<sub>2</sub>O oxidation is larger on a global scale than is indicated by the present model.

The calculations show that very substantial ozone reductions must accompany intense solar-proton events during polarity reversals, and also that the maximum effect is reached 1–2 yr after the event, and the time required for the atmosphere to recover to its initial condition is almost 10 yr. Even in the absence of intense solar-proton events, the ozone content will be reduced by 4.3% by the continuous action of galactic cosmic rays.

The altitude dependence of the ozone reduction is shown in Fig. 3, which indicates that the main effect occurs well above the maximum of the ozone layer, at least near the time of peak reduction. Figure 4 shows the percentage change in the solar heating rate attributable to the absorption of ultraviolet and visible radiation by O<sub>3</sub> and NO<sub>2</sub>. It may, incidentally, be concluded that changes in the Earth's climate may result from intense solar-proton events occurring during polarity reversals. In fact, during very intense events enough NO<sub>2</sub> could be formed in the stratosphere to affect significantly the penetration to ground level of visible radiation in the 400–500-nm range, where NO<sub>2</sub> absorbs radiation rather strongly.

We have shown that intense solar-proton events occurring during polarity reversals may cause large reductions in the atmospheric column content of ozone. The effect of such depletions on living organisms is difficult to estimate, but Fig. 5 gives a rough indication of the magnitude of the effects. Assuming a thickness of the ozone layer of 0.3 cm, and adopting the solar fluxes of Ackerman<sup>19</sup>, the total number of photons incident per cm<sup>2</sup> during an equinoctial day at the Equator has been calculated as a function of wavelength in the 270–320-nm range. Fluxes at each wavelength have been multiplied by a 'relative biological effectiveness' factor<sup>20</sup>, based on the response of protein and nucleic acids to ultraviolet radiation. The calculations show that during a polarity reversal a solar-proton event of the same magnitude as the August 1972 event would increase the effective dose by 15%, and that events 10 and 100 times more intense would increase the dose by 55% and 160%, respectively. Such increases would inevitably have some effect on simple freshwater

Fig. 4 A, Calculated heating rate under normal conditions attributable to the absorption of solar radiation by: a, O<sub>3</sub>; and b, NO<sub>2</sub> ( $\times 10^3$ ). B, Fractional changes attributable to intense solar-proton events and galactic cosmic rays during polarity reversals. The increased heating rates at the lower levels are attributable to the increased penetration of solar ultraviolet radiation when the overlying ozone is depleted.

Fig. 5 The relative effective dose of ultraviolet radiation received on an equinoctial day at the Equator as a function of the depletion in stratospheric ozone.

microorganisms, many of which at present seem to be living close to their maximum tolerance of ultraviolet radiation<sup>14</sup>. The effect on marine organisms is unknown, and will depend on such factors as the length of time spent in the upper part of the euphotic zone, where the ultraviolet dosage will be highest, and on the effect of the increased ultraviolet light on phytoplankton. The total effect on the organisms, however, is certainly an increase in environmental stress, which may, as already mentioned, be sufficient to lead to extinction.

Though the radiolarian extinctions discussed here may have resulted from the addition of one new stress factor to others that existed already, it is perhaps worth speculating that the mechanism we have described may have had the dominant role in some of the massive faunal extinctions that have occurred in the distant past. For example, roughly one-third of all living species became extinct at the close of the Cretaceous, which was a period marked by a resumption of polarity reversals, following a very lengthy period of normal polarity<sup>21</sup>.

In conclusion, it seems that current concern about possible anthropogenic destruction of stratospheric ozone may be well founded, since it is possible that major ozone depletions occurring in the distant past have had a profound effect on the development of life as we know it.

We acknowledge a discussion with F. E. M. Lilley which led to the initiation of this study. The National Center for Atmospheric Research, Boulder, is supported by the National Science Foundation.

# Thickening of the Ross Ice Shelf and equilibrium state of the West Antarctic ice sheet

R. H. Thomas

Ross Ice Shelf Project, University of Nebraska, Lincoln, Nebraska 68588

*Data from the south-east quadrant of the Ross Ice Shelf, Antarctica indicate that, near the grounding line, the ice shelf is growing thicker by almost  $1 \text{ m yr}^{-1}$ . This thickening rate implies an advance of  $1 \text{ km yr}^{-1}$  of the grounding line between the West Antarctic ice sheet and the Ross Ice Shelf. It can be reconciled with independent evidence for current thinning of the West Antarctic ice sheet if the latter is a delayed response to an earlier retreat of the ice shelf grounding line. The high rates of ice shelf thickening may be due to an increase in the resistance to ice shelf movement caused by localised ice shelf grounding following isostatic uplift of the sea bed.*

Most of the West Antarctic ice sheet (Fig. 1) rests on rock that is below sea level now and would still be below sea level if the ice sheet were removed and complete isostatic rebound occurred. Mercer<sup>1</sup> has suggested that such an ice sheet could disintegrate rather rapidly if the surrounding ice shelves were removed, and Hughes<sup>2</sup> noted that the surface profile of the West Antarctic ice sheet (WIS) was not an equilibrium profile and suggested that the ice sheet may currently be disintegrating. Here I shall use measurements made by the Ross Ice Shelf Project (RISP) (refs 3, 4 and H. B. Clausen and W. Dansgaard, personal communication) to examine the state of equilibrium of parts of the Ross Ice Shelf (RIS). I shall correlate this information with other available data to evaluate current behaviour of the WIS.

## Data

The results from RISP are summarised in Fig. 2 where strain rates, accumulation rates, and ice velocities are plotted against distance along the flow line that passes through the site of a proposed bore hole through the ice shelf and into the sea bed. The path of the flow line across the ice shelf was deduced from measurements of ice velocity and surface strain rate<sup>3</sup>. It enters the ice shelf from ice stream 'B' (Fig. 1) and has been extrapolated on to the WIS assuming the ice to be moving perpendicular to the surface contours. The catchment area for ice stream 'B' is also shown in Fig. 1. Snow accumulation rates ( $A$ ) in the catchment area (Fig. 2) are from Bull<sup>5</sup>, and local ice velocities ( $V$ ) have been calculated assuming that ice movement exactly compensates upstream snow accumulation. Vertical strain rates ( $\dot{\epsilon}$ ) in this area were then calculated from the equation of continuity<sup>6</sup>

$$\partial H / \partial t + V \partial H / \partial x = A + B + H \dot{\epsilon} \quad (1)$$

where  $x$  is distance along the flow line,  $H$  is ice thickness,  $\partial H / \partial t$  is the rate of thickening of the ice sheet,  $\partial H / \partial x$  is the thickness gradient along the flow line,  $B$  is bottom freezing rate ( $A$  and  $B$  are expressed as depths of ice per unit time; on the WIS I have assumed that  $|B| \ll |A|$ ) and  $\dot{\epsilon}$  is negative for thinning. To calculate values of  $\dot{\epsilon}$  upstream of the grounding line, I have assumed that in this area  $\partial H / \partial t = 0$ . In the central part of the ice shelf  $A$  and  $V$  values have been interpolated

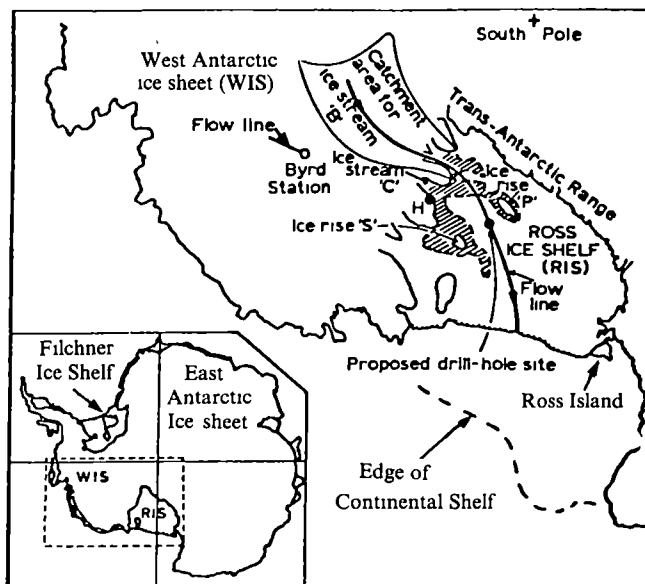

between the RIPS measurements and data from near the ice front<sup>7,8</sup>, and for this region I have assumed zero lateral strain, so that  $\dot{\epsilon} = -\partial V / \partial x$ . This assumption is probably valid near the ice front<sup>7</sup>, but further upstream there may be lateral compression because of converging ice streams. Ice thickness data<sup>4,8-10</sup> are most reliable for the ice shelf section of the flow line.

## Interpretation

The data shown in Fig. 2 has been used to calculate steady-state snow particle paths<sup>11</sup> from where they land on the surface to the point of exit from the ice shelf (Fig. 3). Ice velocity is assumed to be independent of depth, which is true for the ice shelf and is a good approximation for most of WIS, where ice movement is predominantly by bottom sliding<sup>12</sup>. The particle-path results give the relationship between age and depth at all points along the flow line, and Fig. 4 is a plot of age against depth at the site of the proposed drill hole, but inevitably, these ages can be regarded as only approximate. Furthermore, the steady-state assumption (that conditions along the flow line are invariant with time) is a rather drastic restriction. Indeed 10,000 yr ago the WIS probably covered the entire Ross Ice Shelf. Strain rates and ice velocities would then have been considerably smaller than those in Fig. 2. Lower strain rates imply a slower thinning of the annual layers and, even if snow accumulation was lower over a more extensive WIS, the deepest ice is probably younger than shown in Fig. 4.

Where the particle paths leave the base of the ice shelf, bottom melting must occur for the ice shelf profile to be time

**Fig. 1** Part of the West Antarctic ice sheet and the Ross Ice Shelf. In the shaded area, the sea bed is within 50 m of the ice shelf bottom; this entire region may be grounded within the next 200 yr.

Fig. 2 Snow accumulation rate ( $\dot{A}$ ), ice velocity ( $V$ ) and vertical strain rates ( $\dot{\epsilon}$ ) plotted against distance along the flow line that passes through the proposed RISP drill-hole site.

invariant. Similarly, bottom freezing occurs where particles enter the base of the ice shelf. Figure 3 indicates that, for a steady state, appreciable bottom melting is taking place near the junction, or grounding line between the WIS and the RIS, with the bottom freezing nearer the ice front. We should, however, expect the opposite to be true with maximum bottom freezing near the grounding line. Indeed, observations of sediment laden ice near ice rise 'P' (ref. 13), where severe fracturing has probably overturned parts of the ice shelf, suggest that bottom freezing is taking place upstream of the ice rise. Consequently, we relax the steady-state assumption, and use equation (1) to study the non-steady-state behaviour of the ice shelf.

### Non-equilibrium behaviour

Equation (1) has been solved to give  $(\partial H/\partial t - \dot{B})$  for the ice shelf section of the flow line, and the results are given in Fig. 5. Upstream of the drill-hole site  $\dot{B}$  probably has a small positive value, but for simplicity we shall assume that  $\dot{B} = 0$ . Figure 5 then becomes a plot of the rate of ice shelf thickening  $(\partial H/\partial t)$  against distance from the grounding line and, within the limits of observation error,  $\partial H/\partial t$  decreases linearly from  $\sim +1 \text{ m yr}^{-1}$  at the grounding line to zero near the drill-hole site. An interesting effect of this linear decrease in  $\partial H/\partial t$  is that the magnitude of the thickness slope  $|\partial H/\partial x|$  (and thus, from equation (1), of  $\partial H/\partial t$ ) increases with time. Downstream from the drill-hole site the ice shelf appears to be in equilibrium with bottom melting within  $\sim 200 \text{ km}$  of the ice front, as is approximately depicted by the dashed curve. The large deviations from the dashed curve almost certainly arise from over-estimation of the relevant vertical strain rates, which were calculated assuming lateral strain to be zero. In reality there is probably lateral compression from the converging ice streams.

It is important to note that the high rates of ice shelf thickening shown in Fig. 5 near the grounding line were calculated solely from the RISP data and have an accuracy of  $\sim \pm 0.2 \text{ m yr}^{-1}$ . Although this is the only region where we have 'hard' data, the results shown in Fig. 5 are of particular interest since they imply an annual advance of the grounding line in this area of  $\sim 1 \text{ km}$ , and if the ice shelf continues to thicken at its present rate it will run aground on the bed rock, 100 km upstream of the drill-hole site (Fig. 3), in  $\sim 50 \text{ yr}$ . It should be stressed that such rapid thickening is not expected to be typical for the entire grounding line; indeed data from an area where the ice is moving by slow 'sheet flow' ( $H$  in Fig. 1) indicate that the local grounding line is almost stationary. Nevertheless, ice streams are responsible for most of the WIS drainage, and their present behaviour is a good indicator for the probable future behaviour of WIS.

### Interpretation

The high rates of ice shelf thickening near the grounding line are of considerable interest, particularly since other evidence<sup>14-17</sup> suggests that the WIS has thinned appreciably during the past 10,000 yr and may still be thinning. Equation (1) can be solved using measurements from Byrd Station (Fig. 1)<sup>2,12</sup> to give  $(\partial H/\partial t - \dot{B}) \approx -0.4 \text{ m yr}^{-1}$ .  $\dot{B}$  is probably  $< 10^{-2} \text{ m yr}^{-1}$  (ref. 12), so the ice at Byrd Station is currently thinning by  $\sim 0.4 \text{ m yr}^{-1}$ . Upstream from Byrd Station, the available data<sup>2,12</sup> indicate that the vertical strain rate drops, to give a thinning rate of  $\sim 0.1 \text{ m yr}^{-1}$  near the WIS summit.

Analysis of the concentration of microparticles in ice from a bore hole at Byrd Station gives estimates of age as a function of depth<sup>18</sup>. These can be used to derive historical vertical strain rates, and the record for the past 2,000 yr shows good agreement with the recently measured values. For  $\sim 25,000 \text{ yr}$  before 2,000 yr BP, however, vertical strain rates were between 5% and 10% of the present values upstream from Byrd Station. Probable temporal variations in snow accumulation cannot account for this large apparent reduction in strain rates before 2,000 yr BP. Instead, I suggest that a real increase in strain rates took place  $\sim 2,000 \text{ yr}$  ago. If we assume that present-day vertical strain rates ( $\dot{\epsilon} \approx -10^{-4} \text{ yr}^{-1}$ ) upstream of Byrd Station are typical for the past 2,000 yr we can estimate the 2,000 yr BP ice thickness as

$$H = H'/(1 + \dot{\epsilon})^{2,000} \quad (2)$$

where  $H'$  ( $\sim 2,500 \text{ m}$ ) is the present average height above bed rock of the 2,000 yr BP ice surface, giving  $H \sim 3,050 \text{ m}$ , or  $\sim 350 \text{ m}$  thicker than the present ice sheet. This is in agreement with general conclusions from stable isotope analysis of ice from the Byrd Station bore hole<sup>14</sup> and from interpretation of temperatures measured in the bore hole<sup>15</sup>.

Near the summit of an ice sheet  $V\partial H/\partial x \rightarrow 0$  and probably  $\dot{B} \ll \dot{A}$  so equation (1) can be written:

$$\partial H/\partial t \sim \dot{A} + H\dot{\epsilon} \quad (3)$$

With the pre-2,000 yr BP vertical strain rate ( $\sim -10^{-5} \text{ yr}^{-1}$ ) equation (3) gives  $\partial H/\partial t \sim \dot{A} \rightarrow (\dot{A} - 0.03) \text{ m yr}^{-1}$ , for  $H = 0 \rightarrow 3,000 \text{ m}$ . The average value now of  $\dot{A}$  upstream of Byrd Station is  $0.17 \text{ m yr}^{-1}$  (ref. 19), and even assuming a significant

Fig. 3 Steady-state particle paths for the flow line that passes through the proposed RISP drill-hole site. The numbers at the point of origin of each flow line represent the time taken in years to pass each point for a snow particle deposited 20 km downstream from the WIS summit. Sea depth was measured in the RISP area<sup>4</sup> and near the ice front<sup>8</sup>.

Fig. 4 A plot of age as a function of depth at the proposed RISP drill-hole site based on steady-state assumptions. Actual ice sheet behaviour implies that deeper ice is probably younger than shown

reduction in  $\dot{A}$  associated with more widespread glaciation we may conclude that the WIS summit was thickening continuously until  $\sim 2,000$  yr BP, when thinning commenced. This implies that the WIS failed to achieve an equilibrium state, and is compatible with the theory<sup>20</sup> that the WIS can exist only in a state of growth or shrinkage unless its outer margins reach to either a point where the sea has a critical depth or the edge of the continental shelf. It is important to note that the quantitative estimates of ice thickness and rates of thickening before 2,000 yr BP are very approximate, and improvement in their accuracy must await data from drill holes upstream from Byrd Station. It is, however, probably safe to conclude that the ice thickness at the WIS summit 2,000 yr BP was significantly greater than today, and that before 2,000 yr BP the ice sheet had been thickening for  $\sim 25,000$  yr. Moreover, analysis of microparticle concentrations in the Byrd Station bore hole indicates that the basal ice is  $\sim 27,000$  yr old, implying that the WIS grew on a virtually ice-free area to achieve a summit thickness of 3,000 m over a period of  $\sim 25,000$  yr. This time period is in fair agreement with theoretical estimates of ice sheet growth rate<sup>21</sup>. Independent evidence<sup>16, 22</sup> suggests that the WIS extended almost to the edge of the continental shelf until  $\sim 10,000$  yr BP, when recession commenced, and ungrounding had occurred in the Ross Island area (Fig. 1) by 6,000 yr BP. Theory (R. H. Thomas, in preparation) indicates that the retreat of the WIS grounding line would proceed rather slowly until it reached Ross Island, when retreat rates would increase to  $> 1$  km yr<sup>-1</sup>. Thus WIS recession could have ceased by  $\sim 4,500$  yr BP, implying that the thinning of the ice sheet summit now observed is a delayed response to the retreat of the grounding line.

### Connection with RISP data

We must now reconcile these conclusions with the RISP observations that imply thickening at the point where ice stream 'B' enters the ice shelf. This thickening must have commenced after the period of major recession, as a consequence of either increased outflow or increased upstream constraint acting on the ice shelf near the grounding line. Increased outflow could result from upstream thinning or from enlargement of the catchment area to include that of ice stream 'C', which currently seems to be relatively inactive. We might, however, expect that present-day outflow rates are appreciably less than those during the stage of maximum recession when the ice shelf was thinning. So we shall examine the second alternative, that upstream constraints on the ice shelf increased during the past 4,500 yr

causing a decrease in the magnitude of ice shelf strain rates and, from equation (1), a positive thickening rate.

At present, the ice shelf in this area is constrained by ice rise 'P' (Fig. 1), an area where the ice shelf has grounded. Removal of the ice rise would allow more rapid ice shelf thinning and probably a grounding line recession in the south-east corner of the RIS. Thus, we can explain the present ice shelf thickening if we assume that grounding of ice rise 'P' took place comparatively recently, after isostatic uplift of the sea bed. An ice sheet completely covering the RIS would have depressed the sea bed in the area of ice rise 'P' by several hundred metres and, for a sufficiently rapid recession, much of this depression could persist until most of the present RIS had formed. Thereafter, isostatically uprising sea-bed highs could ground the ice shelf, thereby restricting continued recession of the WIS, and possibly initiating an advance of the grounding line. Evidence to support this suggestion is provided by the dimensions of ice rise 'P'. An approximate estimate of the relationship between the surface elevation and area appropriate to an ice rise can be expressed<sup>23</sup> in terms of the snow accumulation rate, the ice flow-law parameters and temperature-depth curve for the ice rise. Using current accumulation rates (H. B. Clausen and W. Dansgaard, in preparation), theoretical temperatures<sup>24</sup> and ice shelf flow-law parameters<sup>25</sup>, the equilibrium summit elevation for ice rise 'P' is found to be  $\sim 200$  m greater than observed, indicating that the ice rise is probably growing. Moreover, solution of equation (1) using data from the partially grounded ice shelf upstream of ice rise 'S' (Fig. 1) gives thickening rates up to  $0.5$  m yr<sup>-1</sup>, if we assume no bottom freezing. The ice thickness in this area is approximately equal to that of nearby freely floating ice shelf, and it seems likely that local grounding has only recently taken place. The shaded area of ice shelf in Fig. 1 indicates where the sea bed is within 50 m of the bottom of the ice shelf. If the ice shelf continues to thicken at the rates calculated above, then the WIS will advance to cover most of this

Fig. 5 A plot of  $(\partial H/\partial t - \dot{B})$  against distance from the ice shelf grounding line for the flow line that passes through the proposed RISP drill-hole site.  $\partial H/\partial t$  is the thickening rate for the ice shelf, and  $\dot{B}$  is the bottom-freezing rate. Observation errors in the RISP data limit accuracy of corresponding values of  $(\partial H/\partial t - \dot{B})$  to  $\pm 0.2$  m yr<sup>-1</sup>. Near the grounding line  $\dot{B}$  probably has a small positive value and the plot indicates a rather high rate of ice shelf thickening in this area.

area within the next 200 yr. Further advance will then be delayed by the probable lack of grounded areas in the western part of the ice shelf.

Isostatic uprise rates were at a maximum immediately following removal of the ice load, and the grounding of ice rise 'P' probably occurred shortly after the WIS recession, or ~ 4,000 yr ago. Before grounding, the local ice shelf was probably ~ 500 m thick, with its base ~ 450 m below sea level. The present bed rock high beneath the ice rise 'P' is ~ 250 m below sea level, giving an uplift of 200 m during a period of ~ 4,000 yr. Thus, the average uplift rate is ~ 0.05 m yr<sup>-1</sup> compared to a current uplift rate of 0.01 m yr<sup>-1</sup> in Fennoscandia, where the remaining uplift<sup>26</sup> is of a similar magnitude to that estimated<sup>27</sup> for the sea bed beneath the RIS. Estimates of remanent uplift are, however, subject to rather large errors, and the RIS area may be appreciably further from equilibrium than Fennoscandia. Moreover, differences in crustal thickness could result in larger uplift rates beneath the RIS.

## Conclusions

The WIS recession that began ~ 10,000 yr ago was probably initiated by the rise in sea level associated with melting of the northern ice sheets, but we should also consider the possibility of isostatic depression of the sea bed triggering recession of the grounding line. Theory<sup>20</sup> predicts that an ice sheet grounded below sea level exists in equilibrium when outflow because of snow accumulation on the ice sheet is balanced by movement of ice across the grounding line into a surrounding ice shelf. This occurs at a critical sea depth  $D$ , which is a function of ice sheet diameter, snow accumulation rate and the flow properties of ice. The ice sheet grows if sea depth is  $< D$ , and it recedes if sea depth is  $> D$ . For a growing ice sheet, isostatic depression of the bed rock continues after the grounding line has reached the appropriate critical sea depth. Moreover, crustal rigidity would cause downwarping of the sea bed for an appreciable distance to seaward of the grounding line. Consequently, sea depth at the grounding line may ultimately exceed  $D$  and trigger ice sheet recession.

If growth and decay of WIS is controlled by isostatic movements of the sea bed then we may tentatively conclude: first, that the growth rate and maximum extent of the ice sheet are determined by snow accumulation rates and sea bottom topography. Second, that the longevity of the ice sheet is determined by the rate of isostatic depression of the sea bed near the

ice sheet-ice shelf junction. Third, that after a slow start, recession proceeds very rapidly until the ice shelf formed around the shrinking ice sheet is grounded by isostatically uprising sea bed highs. Thereafter, recession is slowed and may give way to a period of ice sheet growth. Thus the minimum size of the WIS is determined by the availability of suitable obstructing ice rises and, on a sufficiently flat sea bed, almost complete disintegration of the WIS is possible. The bottom topography is, however, altered by erosion and deposition during ice sheet growth and decay so that each cycle of growth and recession follows an individual pattern that is determined by the prevailing sea bed topography. Fourth, that climatic changes probably have only a minor effect on the growth-decay sequence of the WIS. The converse may, however, not be true. In particular, complete disintegration of the WIS may alter world climate sufficiently to initiate a glacial epoch<sup>28,29</sup>.

# Amino acids in modern and fossil woods

Cindy Lee\*

*Amino acids have been found in fossil woods. The extent of amino acid racemisation increases with the age of the wood. The degree of racemisation of proline and hydroxyproline in wood from Kalambo Falls, Zambia, was used to estimate an age of >110,000 yr for the Acheulian-Sangoan transition.*

Wood is found preserved in many geological formations. Wooden tools and artefacts have also been found at many

archaeological sites. The radiocarbon dating method was first applied to a wooden artefact, an acacia wood beam recovered from the tomb of King Zoser in Sakkara, Egypt<sup>1</sup>. Radiocarbon dating however cannot be used for objects  $\gtrsim 40,000$  yr old. A wood-dating technique capable of extension beyond this present limit would be extremely useful to both anthropologists and geologists, and amino acid racemisation may provide such a technique.

The dating of fossil materials using the racemisation of amino acids is becoming well established. The kinetics and mechanism of the amino acid racemisation reaction and the use, problems and criticisms of this reaction in dating fossil materials have been discussed elsewhere<sup>2,3</sup>. The method was applied to deep-sea sediments, and fossil bones and shells<sup>2,3</sup>.

\*Present address: Woods Hole Oceanographic Institution, Woods Hole, Massachusetts 02543.

Also, racemisation in tooth enamel has been used to assess the ages of living mammals<sup>4</sup>. These applications all involve racemisation in inorganic matrices such as calcium carbonate and calcium phosphate, but racemisation has also been shown to occur in an organic matrix, coprolites<sup>5</sup>.

Wood has an organic matrix composed mainly of cellulose, but with a complex biochemical composition because of the numerous biological processes occurring within the tree<sup>6,7</sup>. Modern woods are known to contain amino acids<sup>8-11</sup>, but there have been no investigations of the concentrations and enantiomeric composition of amino acids in fossil woods. We report here the amino acid composition and extent of racemisation in several modern and fossil woods, and a possible interpretation of these results. We emphasise that, because of the complexities and variabilities of plant biochemistry and the paucity of data on modern and fossil woods, this interpretation is preliminary.

## Method

The modern and fossil woods we have investigated are listed in Table 1. The samples were first cleaned by ultrasonication in doubly-distilled water to remove surface dirt, and were then carefully broken up into small pieces. After being rinsed in 2 N HCl, the pieces were hydrolysed in excess doubly-distilled 6 N HCl for 24 h. The hydrolysate was centrifuged to remove suspended materials, evaporated to dryness, and the residue desalted on Dowex 50W-X8 (100-200 mesh). Part of the sample was analysed on the Beckman-Spinco Model 118 Automatic Amino Acid Analyser to determine the total amino acid composition. Another fraction of the sample was analysed for enantiomeric ratios either by preparing diastereomeric dipeptides using a modification<sup>13</sup> of the method of Manning and Moore<sup>12</sup>, or by gas chromatography of the N-trifluoroacetyl (+)-2-butyl esters<sup>14</sup>.

## Total amino acid concentration

The total amino acid analyses (excluding basic amino acids) are shown in Table 1. Several interesting features are apparent. First, the total amino acid concentration per g of dry wood decreases with the age of the sample. This may arise from the hydrolysis of the bound amino acids to free amino acids (or decomposition to other organic compounds). Free amino acids, being more mobile, are later removed from the wood. A similar mechanism accounts for the loss of amino acids in fossil bones<sup>16</sup>. To demonstrate that the amino acids in fossil

woods are in the bound rather than in the free state, cleaned, sonicated wood slivers of bristlecone pine were stirred at room temperature for 60 h in 6 N HCl. After this treatment, the HCl solution was evaporated, and analysis of the remaining residue indicated the presence of few, if any, amino acids. Acid hydrolysis of the same slivers, however, yielded amino acids.

## Amino acid ratios

Another trend shown in Table 1 is the change in the relative ratios of the amino acids with time. With increasing age, the amounts of aspartic acid, threonine, and serine decreases relative to valine, while the relative amounts of isoleucine, leucine, and glutamic acid remain approximately constant. Proline is one of the most stable amino acids, and becomes predominant in the older woods. In both Kalambo Falls samples, proline constitutes ~ 25% of the total amino acid present. Kinetic studies carried out by heating samples of bristlecone pine to high temperatures, predict an amino acid stability pattern similar to that observed in the fossil woods<sup>17</sup>. This suggests that the amino acids in the fossil woods are indigenous.

The results listed in Table 1 also show that 4-hydroxyproline is present in wood. This amino acid has a fairly limited occurrence in nature and is found only in structural proteins such as collagen<sup>18</sup>. The cell walls of higher plants contain a hydroxyproline-rich glucoprotein, extensin<sup>19</sup>. This structural protein is probably the source of hydroxyproline and perhaps some of the other amino acids in wood. There is a gradual decrease in the hydroxyproline content of wood with age; a similar decrease is seen in fossil bones<sup>20</sup>.

## Enantiomeric ratios

Amino acid enantiomeric ratios for the various wood samples are shown in Table 2. In every case, the amount of racemisation increases in the order bristlecone pine < Sangoan < Acheulian. There is an unexplained discrepancy between the D/L aspartic acid ratios determined by the diastereomeric dipeptide and the gas chromatographic techniques for the Acheulian sample, but the order and the direction of increase are the same. (This is the first time we have found such a discrepancy between the two methods. This difference probably occurs because the Acheulian sample contains low quantities of the normal protein amino acids and fairly substantial amounts of unknown compounds which appear mainly in the gas chromatographic trace.) The

**Table 1** Amino acid composition of modern and fossil woods ( $\mu\text{mol per g dry wood}$ )

	Modern cherry trunk	Modern walnut root	Bristlecone pine (TRL-63-53)	Kalambo Falls Sangoan	Kalambo Falls Acheulian
Asp	1.43	1.35	0.68	0.35	0.05
Thr	1.04	0.79	0.49	0.25	0.03
Ser	1.05	1.00	0.57	0.22	0.03

Tyr	0.26	0.13	0.09	0.28†	0.13†
$\phi$ -Ala	1.01	0.59	0.30	—	—
Total	12.91	10.50	6.46	3.89	0.87
Age	0	0	4,220 yr‡	> 40,000 yr§	≥ 60,000 yr

\*OH-Pro values were determined by using approximate OH-Pro/Pro values from GC analysis. Values were not determined for modern woods but the amino acid analyser results indicate OH-Pro is certainly present.

†The analyser peaks for the Sangoan and Acheulian samples were integrated by machine. Since tyrosine and phenylalanine eluted very close to one another, their integrated peak areas were not differentiated. The chromatograms show that the Tyr/ $\phi$ -Ala ratio is the reverse of that in the younger woods. This is surprising and may be due to a larger unidentified peak eluting very close to tyrosine.

\*The D and L peaks of these two amino acids were analysed by combined gas chromatography-mass spectrometry to verify the absence of interfering peaks.

†Determined on amino acid analyser at SIO. All other values were determined by gas chromatography at NASA.

‡Not possible to determine because of interfering peaks.

increasing racemisation of the amino acids with increasing age of the wood indicates that the amino acids are indeed indigenous.

### Comparison of wood with bone and solution ratios

The relative racemisation rates of amino acids in wood seem to be different from those in bone and in aqueous solution<sup>2</sup>. The data in Table 2 indicate that proline has the fastest racemisation rate in wood. Proline also has a fast rate in aqueous solution (J.L.B., unpublished), whereas in bone its racemisation rate is comparable to that of alanine and glutamic acid (J.L.B., K. A. Kvenvolden, and E.P., unpublished). Aspartic acid, which has the fastest racemisation rate in bone and in aqueous solution, racemises at about the same rate as, or perhaps even slower than, glutamic acid in wood. Based on the Acheulian results, isoleucine epimerisation in wood seems to be slower than the racemisation of valine and leucine. All three of these amino acids have nearly the same racemisation rates in bone and in aqueous solution. The gas chromatogram of the Acheulian sample showed numerous unidentified peaks eluting near valine, alanine, leucine and serine, and it is possible that spurious peaks caused erroneous D/L ratios for these amino acids.

Based on analyses of bones from sites in east and south Africa, racemisation in wood seems to be much slower than in bone<sup>21,22</sup>, and to confirm this, high temperature kinetics experiments were carried out. Bristlecone pine samples (TRL-71-3, ~ 3,170 yr) were used in these studies, rather than modern wood. Modern woods behaved very differently during these experiments, and had high D/L aspartic acid ratios (0.16 and 0.12). Modern wood tended to stain glassware and smoke profusely during acid hydrolysis, whereas the older woods did not (probably because of the absence of sap). The sap of modern woods has been shown to contain free amino acids<sup>10</sup>, whereas free amino acids are absent in the bristlecone pine sample. The bristlecone pine behaved more like the fossil woods during these experiments. Apparently the organic substances present in the wood sap are labile and have decomposed or have diffused out of the wood after 3,000 yr.

The kinetics experiments run on bristlecone pine (TRL-71-3) showed that the epimerisation of isoleucine follows reversible first-order kinetics<sup>17</sup>. The first-order rate for conversion of isoleucine to alloisoleucine,  $k_{iso}$ , was determined at several temperatures. These results, along with the  $k_{iso}$  values in aqueous solution<sup>23</sup> and bone<sup>24</sup>, are shown in Fig. 1. The high temperature results confirm that the racemisation rates in wood are much slower than those in bone or in aqueous solution ( $k_{iso, bone} \approx 10 \times k_{iso, wood}$ ). The Arrhenius activation energy in wood, 29.4 kcalorie mol<sup>-1</sup>, is similar but slightly lower than in bone ( $E_a = 33.3$  kcalorie mol<sup>-1</sup>) or in aqueous solution ( $E_a = 31.3$  kcalorie mol<sup>-1</sup>).

### Interpretation

The slower racemisation rate in wood may occur because the amino acids in wood are bound in an organic matrix. Since racemisation requires the presence of water<sup>20,21</sup>, a hydrophobic environment in wood could slow down the racemisation rate—

bones impregnated with tar have racemisation rates considerably slower than bones in normal geological environments<sup>16</sup>. Racemisation studies in coprolites, also an organic matrix, similarly show rates of racemisation slower than bones from the same location (J.L.B., and M. G. Petit, unpublished). One important difference between the isoleucine epimerisation kinetics in wood and those of other systems, is that the equilibrium allo/iso ratio is 0.86 in wood, compared with 1.25–1.40 for aqueous solution and bone<sup>20,21</sup>. Again, this difference may arise from the organic nature of the wood.

### Ages

The racemisation results we have obtained for the Kalambo Falls woods can be used to calculate an age for the upper Acheulian industry at this site. The racemisation dating technique is best applied by 'calibrating' the rate of the amino acid racemisation reaction for a particular site using the extent of racemisation in a sample which has been radiocarbon dated. After this 'calibration' has been carried out, other samples from the same site can be dated based on the extent of their

Fig. 1 Arrhenius plot of isoleucine-alloisoleucine epimerisation kinetics in wood, in aqueous solution<sup>23</sup> and in bone<sup>24</sup>.

racemisation. The ages of fossil bones deduced using this technique are in close agreement with radiocarbon ages and the ages deduced from other evidence<sup>21,22</sup>.

Our Sangoan sample was radiocarbon dated at > 40,000 yr old. Therefore, by using the Sangoan sample to calibrate the racemisation rate in wood at Kalambo Falls, only a minimum age can be assigned to the Acheulian sample. Calculations of this minimum age can be made using the enantiomeric ratios from each of the amino acids appearing in Table 2. Certain amino acids, however, are better than others. Aspartic acid is unsuitable because of the discrepancy between the D/L ratios determined using the gas chromatographic and diastereomeric dipeptide techniques. Because of the very small extent of racemisation of valine, leucine, phenylalanine and isoleucine in the Sangoan sample, it is difficult to calculate accurate calibration rate constants. The best choices for the calibration procedure are proline and hydroxyproline. Proline is the most stable amino acid in wood, and is still present in sizeable amounts in older woods (see Table 1). Proline also has the fastest racemisation rate, according to our preliminary data. Hydroxyproline is also a good choice for use in the calibration method because it has a much different (10 times slower) rate of racemisation (epimerisation) than proline, and it is not subject to contamination problems, because of its limited occurrence in nature.

Amino acid racemisation ages and the calibration rate constants are calculated from the following equation<sup>2</sup>

$$\ln \left\{ \frac{1 + (D/L)}{1 - K'(D/L)} \right\} \bigg|_{\text{sample}} - \ln \left\{ \frac{1 + (D/L)}{1 - K'(D/L)} \right\} \bigg|_{t=0} = (1 + K')kt$$

where  $k$  is the first-order rate constant for interconversion of the D- and L-enantiomers of a particular amino acid and  $K'$  is the inverse of the equilibrium constant  $K_{eq}$ , which equals the D/L ratio at equilibrium<sup>2</sup>. For amino acids with more than one centre of asymmetry, such as hydroxyproline,  $K_{eq}$  is slightly different from unity. Experimental determinations of  $K_{eq}$  for hydroxyproline show that the equilibrium constant in aqueous solution is 0.8 (ref. 20). Since hydroxyproline epimerisation in the fossil wood samples we have analysed, is so far from equilibrium, the value of  $K_{eq}$  makes little difference to our calculations. Using the D/L-proline and allohydroxyproline/hydroxyproline ratios determined for the Sangoan wood sample, an age of > 40,000 yr for the Sangoan, and the bristlecone pine at  $t = 0$  values, the calculated racemisation rates are  $k_{OH-P_{ro}} \leq 6.5 \times 10^{-7} \text{yr}^{-1}$  and  $k_{P_{ro}} \leq 6.0 \times 10^{-6} \text{yr}^{-1}$ . These values of  $k$ , combined with the D/L proline and allohydroxyproline/hydroxyproline ratios for the Acheulian wood, give ages of > 110,000 yr for hydroxyproline and > 110,000 yr for proline. The agreement of these two values is excellent,

especially considering the order-of-magnitude difference in rate constants. It should be pointed out that similar calculations using the other amino acids listed in Table 2 all give older minimum ages. The ages deduced from the other amino acids are less reliable, however, for the reasons we have discussed earlier. In any case, the combined racemisation results show that > 110,000 yr is an absolutely minimum age for the Sangoan-Acheulian transition at Kalambo Falls.

The age of the end of the Acheulian industry in Africa has sometimes been used to define the beginning of the Upper Pleistocene, a time span poorly defined by geochronometric means<sup>26</sup>. (The Upper Pleistocene is more usually defined as coincident with the beginning of the Last (Eemian) Interglacial at ~ 125,000 yr (ref. 26).) Our racemisation-deduced age of > 110,000 yr at Kalambo Falls is consistent with numerous radiometric dates for older Acheulian sites in Africa<sup>25</sup>, and compares well with geologically-inferred dates for the beginning of the Eemian and the end of Acheulian industry in southern Africa<sup>27</sup>.

We thank J. Desmond Clark for suggesting our work on the Kalambo Falls site, for providing us with samples, and for his comments on the manuscript. We also thank Rainer Berger for radiocarbon dating of the Sangoan wood, Hans Suess and Tim Linick for providing us with the samples of bristlecone pine, and John Turk for the modern wood samples. This research was supported by the NSF.

## letters to nature

### UBVRI photometry of Nova Cygni 1975

MULTICOLOUR photometric observations have been made of Nova Cygni 1975. A periodic variation of ~3.2 h was detected by Tempesti<sup>1</sup> on 1975 September 14 when the nova was at  $m_v = 6$ . On 1975 September 18 we made a 4-h survey in five colours, UBVRI, to check this variation using the 40-cm telescope of the Laboratorio di Astrofisica Spaziale CNR at Frascati, in the Monte Porzio Observatory. The

variation was confirmed for all colours, and other significant characteristics of the light curve have been detected.

The photoelectric photometer used, the DAPHNE system, has been described elsewhere<sup>2</sup>; its main features are: the photomultiplier used is the RCA C31034A in photon counting mode, with the GaAs photocathode cooled to -20 °C, measurements in the five bands are serial with the possibility of choice of acquisition time; and each sequence of measurements can be started with a quartz clock at a well

defined time. An electronic offset device switches the telescope from the comparison star to the nova, and vice versa; so that data from the comparison star and nova can be obtained with a minimal interval. The acquisition time was 3 s for each band, and the magnitudes in the five colours have been plotted and are shown in Fig. 1a.

All the light curves show a variation  $\sim 0.08$  mag. Moreover, a new feature is present in every band: a secondary minimum appears centred at 22 h 05 min, shifted  $\sim 110$  min from the maximum. The relative intensity of this anomalous absorption varies with colour, vanishing towards the long wavelength end.

Measurements of the comparison star, BDA473294, with respect to a set of standard stars on September 18 are shown in Fig. 1b. The error bar of each measurement ( $\pm 0.01$  mag r.m.s.) was derived from a check on standard stars. The magnitudes in the five bands derived for the comparison star are:  $U=7.49$ ,  $B=7.48$ ,  $V=7.43$ ,  $R=7.54$ ,  $I=7.69$ , which have been used as a standard for computing the nova magnitudes. No periodic variation was detected, in either magnitude or colour for the comparison star. The same variation of luminosity of the nova is still obtained after applying the coefficients for the night obtained from standard star measurements (see Fig. 1c). This excludes any possibility of intrinsic variation in the comparison star and confirms the short time variation of the nova.

Figure 1d shows the results for September 17 and 18 together. The decrease of the mean intensity is evident, with a rate of almost  $0.1 \text{ mag d}^{-1}$ . Any period from 3 h 00 min to 3 h 48 min fits the two sets of measurements:

Fig. 1 a, Five colour, 4-h photometry of Nova Cygni 1975, on September 18, 1975. b, V and R photometry of the comparison star, obtained from standard stars. c, V and R photometry of the nova, obtained from standard stars. d, B, V, R photometry of the nova for the nights of September 17 and 18.

this implies either different features from night to night, or a real period  $> 3 \text{ h } 48 \text{ min}$ .

We are grateful to Professor P. Tempesti for prompt communication on this atypical feature of the nova.

## Coronal lines in near infrared spectrum of Nova Cygni 1975

WE have been monitoring the 2- and 3- $\mu\text{m}$  spectral regions of Nova Cygni 1975 at irregular intervals. Shortly after maximum, these spectral regions were dominated by the lines of hydrogen and a few of neutral helium superposed on a continuum presumably of free-free radiation. These spectra could be quantitatively interpreted on traditional recombination theory<sup>1</sup>, assuming a temperature of  $\sim 10^4$  K. Beginning with a spectrum

obtained on September 29, 1975 a number of additional lines have appeared in the spectrum. These new lines have increased in strength so that in our most recent data they nearly dominate these spectral regions. These two phases of the spectral development of Nova Cygni 1975 are illustrated for the 2- and 3- $\mu$ m spectral regions in Figs 1 and 2.

To isolate more clearly the additional spectral features, we have subtracted the earlier data, suitably scaled, from the most recent spectra. These difference spectra, also displayed in Figs 1 and 2, demonstrate that the spectral changes result from additional lines superposed on a nearly-unaltered recombination spectrum.

The derived wavelengths and proposed identifications for these new lines are listed in Table 1. The near infrared spectrum of Nova Cyg 1975 is now dominated by forbidden lines arising from highly ionised species of Mg, Al, and Si. These lines are analogous to the coronal lines observed in the visible portion of the solar spectrum. One of them, the [Mg VIII] line at 3.03  $\mu$ m, has been previously observed in the solar corona<sup>2,3</sup>. Although at first sight outlandish, these identifications appear entirely secure. None of the wavelength differences is larger than might be expected on the basis of our error in measuring the wavelength and the expected uncertainties in the predicted wave-

Fig. 1 The 1.9–2.5  $\mu$ m spectrum of Nova Cygni 1975 observed with an InSb detector and a circular variable interference filter having a resolution of 1.3%. The coronal lines are unresolved at this resolution. The difference spectrum in the lower panel results from subtraction of the 1975 September 12 data (top) divided by 18, from the 1975 October 27 spectrum (middle). The emission features near 2.10 and 2.14  $\mu$ m are probably artefacts of this procedure.

Fig. 2 The 2.8–4.1  $\mu$ m spectrum of Nova Cygni 1975 observed with an InSb detector and a circular variable interference filter having a resolution of 2.2% on the same dates as in Fig. 1. The difference spectrum was obtained in the same manner as that in Fig. 1.

lengths. Even more convincing is the fact that virtually all the coronal lines expected in these portions of the spectrum are present. Considering  $\Delta J = 1$  transitions within the ground state of ions of elements whose normal abundance is  $> 10^{-6}$  that of hydrogen, only two predicted lines are not definitely present. One, the line at 4.09  $\mu$ m for [Ca VII], is inextricably blended with Brackett  $\alpha$  at 4.05  $\mu$ m. The other, at 2.29  $\mu$ m, would come from [Ca XIII] whose ionisation potential of 726 eV adequately explains its absence.

This result has a number of interesting consequences. Since these coronal lines have been increasing in absolute strength, a region with very high temperature,  $\sim 10^6$  K, must be developing within the nova material. Furthermore, our data indicate that the degree of ionisation is still increasing, as the [Al IX] and [Si IX] lines have been increasing more rapidly than the other coronal lines. The visible spectrum of Nova Cyg 1975 does not yet, however, exhibit any coronal lines (J. Cohen, personal communication) although coronal lines have been observed in a number of previous novae<sup>4</sup>. Apparently, for reasons that are not yet clear, the near infrared provides a more sensitive indicator of the presence of a coronal zone than does the visible spectrum. This raises the possibility that the development of a very high temperature zone in novae is more common than presently deduced from visible data alone.

Table 1 Coronal line identifications in Nova Cygni 1975

$\lambda_{\text{obs}}(\mu\text{m})$	$\sigma$	$\lambda_{\text{pred}}(\mu\text{m})$	Identification		
1.959	0.007	1.963 (ref. 6)	[Si VI]	$^2P_0$	(1/2, 3/2)
2.040	0.007	2.045 (ref. 6)	[Al IX]	$^2P_0$	(3/2, 1/2)
2.32	0.02	2.323 (ref. 7)	[Ca VIII]	$^2P_0$	(3/2, 1/2)
2.474	0.007	2.481 (ref. 5)	[Si VII]	$^3P$	(1, 2)
2.879	0.014	2.904 (ref. 6)	[Al V]	$^2P_0$	(1/2, 3/2)
3.021	0.014	3.030 (ref. 6)	[Mg VIII]	$^2P_0$	(3/2, 1/2)
3.18	0.03	3.210 (ref. 8)	[Ca IV]	$^2P_0$	(1/2, 3/2)
3.661	0.014	3.656 (ref. 5)	[Al VI]	$^3P$	(1, 2)
3.72	0.02	3.700 (ref. 5)	[Al VIII]	$^3P$	(2, 1)
3.92	0.02	3.917 (ref. 5)	[Si IX]	$^3P$	(1, 0)

Finally, since a number of ionisation stages are observable for Si and Al, we may be able ultimately to deduce the physical conditions within the coronal zone. This raises the exciting prospect of being able to deduce relative elemental abundances for the high temperature component. One might expect the high temperature zone to be more intimately involved with the source of the explosion, and thus its chemical composition may contain important clues for our understanding of the nova process.

## Formation of iron sulphide in solar nebula

IODINE–XENON dating has established that iron sulphide in the Orgueil carbonaceous meteorite is one of the oldest known meteoritic mineral phases, and probably dates from the condensation stage of the early Solar System<sup>1</sup>. This sulphide, although generally assumed to be troilite, FeS, is in fact the Fe-deficient monosulphide, pyrrhotite,  $(\text{Fe,Ni})_9\text{S}_{10}$ , containing ~1 weight % Ni (ref. 2). The purpose of this note is to suggest that such mineral chemistry is inconsistent with equilibrium condensation, and that the course of condensation may have been modified by kinetic effects.

Strictly, iron sulphide is not a condensate but a reaction product between a condensate, metallic Fe, and S in the gas phase. The reaction

goes to the right at 680 K, in a cooling nebula of solar composition<sup>3</sup>. It is necessary to consider the effect of Ni on this reaction and the course of equilibrium condensation may be determined by means of the Fe–Ni–S ternary phase diagram (Fig. 1). This shows that the solar composition lies within the kamacite–taenite–troilite stability field at 680 K. Thus, formation of troilite, which can contain no more than 0.5 weight % Ni (ref. 4), from kamacite containing 6 weight % Ni would require precipitation of taenite, with ~40 weight % Ni (ref. 4). Consequently, with the

commonly accepted value of 1.7 for the solar Fe/S ratio<sup>6</sup>, the only iron sulphide predicted to exist at equilibrium is stoichiometric troilite, FeS, containing <0.5 weight % Ni. It is therefore pertinent to ask why the Orgueil sulphide differs in both crystal structure and Ni content from the predictions of equilibrium condensation. Four possible reasons may be advanced.

First, the value taken for the solar Fe/S ratio may be in error. A value of <1 could result in pyrrhotite being a stable phase. Depending on the actual value of Fe/S, this pyrrhotite would either be accompanied by another sulphide (either pentlandite or pyrite) or fall compositionally within the monosulphide solid solution field. In this last case, the composition of the mineral would be exactly equal to the solar proportions of the three elements. Unless the value taken for the solar Fe/Ni ratio is also in error, in the opposite sense, such is not the case for Orgueil pyrrhotite (Fig. 1) nor does the meteorite contain any pentlandite or pyrite.

Second, stabilisation of another Fe-bearing phase could result in competition for the available Fe and consequent formation of an Fe-deficient sulphide. At around 680 K the only plausible alternative is production of fayalitic olivine from enstatite

At this temperature, however, the maximum possible FeO content of olivine in equilibrium with the nebular gas is ~5 weight %, which is inadequate to alter the course of sulphide condensation. In addition, this reaction is between two solid phases and is unlikely to compete effectively with the gas–

Fig. 1 Phase relations in a portion of the Fe–Ni–S system in equilibrium with vapour at 680 K and  $\leq 1$  atm pressure, based on refs 4, 5. Large circle represents solar composition<sup>6</sup>, small circle shows composition of Orgueil pyrrhotite<sup>2</sup>. MSS is monosulphide solid solution, FeS<sub>2</sub> is pyrite; FeS is troilite,  $(\text{Fe,Ni})_9\text{S}_8$  is pentlandite,  $\alpha$  is kamacite, body-centred cubic Fe;  $\gamma$  is taenite, face-centred cubic Fe

solid reaction. It would also result in a sulphide with a Ni/Fe ratio greater than solar, rather than less, because meteoritic olivines contain only trivial amounts of Ni.

A third possibility is that oxidation<sup>8</sup> of a Ni-poor troilite condensate might have produced the observed Ni-bearing pyrrhotite, if the Ni was retained in a sulphide phase comprising a small fraction of the original S. Several reaction pathways are possible; the observed Orgueil mineralogy (pyrrhotite plus magnetite plus epsomite, MgSO<sub>4</sub>) suggests the following representation

It is far from certain, however, that such a reaction could have occurred. If it did occur it must have been after accretion of the meteoritic parent body to retain the oxidised species of sulphur. Therefore the <sup>129</sup>I/<sup>127</sup>I ratio inferred by Lewis and Anders<sup>1</sup> would have been characteristic of some late stage in planetary accretion rather than of the condensation stage, as they propose. Such a conclusion would impose severe constraints on models of early Solar System accretion, especially as accumulation of the other meteorite parent bodies apparently took place after the Orgueil alteration stage<sup>1</sup>. Another argument against the oxidation hypothesis is that pyrrhotite-magnetite associations are virtually never found in Orgueil. Where alteration of pyrrhotite is found, the reaction products are sulphate, elemental sulphur and limonite (an hydrated iron oxide of variable composition).

A more reasonable possibility is that sulphide formation in the nebula was inhibited by sluggish diffusion, so that sulphur began to react with previously condensed troilite to form pyrrhotite

This reaction is also capable of explaining qualitatively the Ni content of Orgueil pyrrhotite. Initial formation of troilite would have resulted in the enrichment of Ni in the metal at the interface with the growing sulphide<sup>4</sup>. Conversion of this sulphide to pyrrhotite, which can accept large amounts of Ni and in which diffusion is likely to be easier than in either troilite or kamacite, would result in transfer of some Ni from metal into sulphide. The amount of such Ni would presumably have been kinetically limited.

Observations on Orgueil sulphides therefore suggest that below ~700 K the course of solar system condensation was modified by kinetic effects and that equilibrium may not have been achieved. These conclusions have implications for the Bi, Tl, In cosmo-thermometers which are considered to be applicable over the temperature range 420–500 K (refs 9, 10). In fact, the reactions considered here are particularly appropriate because Bi and Tl are believed to condense as alloys in metallic Fe, and In as a sulphide in troilite. If sulphur failed to reach equilibrium with Fe at 680 K, it is difficult to understand how Bi and Tl could have done so at a temperature 200 K below. Recall that, by then, all available Fe would be covered with a layer of pyrrhotite. A final detail is that the solubility data used in the thermodynamic calculations, on which the equilibrium theories are based, were for troilite rather than pyrrhotite, in which heavy trace elements are probably more soluble than in stoichiometric troilite.

Identification of Orgueil pyrrhotite as a nebular condensate is also in conflict with predictions of Blander's Constrained Equilibrium Theory<sup>11</sup>, where, as a result of inhibited nucleation of metallic Fe and FeS, troilite is predicted to condense at temperatures in the range 1,050–1,450 K. At such high temperatures it is unlikely that reaction (1), once nucleated, would fail to reach equilibrium.

These conclusions apply strictly only at the formation location of the carbonaceous meteorites. In the absence of evidence to the contrary, such as, hypothetically, occurrence of primordial troilite in some other type of meteorite, they may be applied to condensation at any point in the Solar System swept by the 680 K isotherm.

## Atmospheric shock waves and condensation clouds from Ngauruhoe explosive eruptions

VISIBLE shock waves ('flashing arcs') passing through the air above a volcanic vent were first recognised by Perret<sup>1</sup> during explosive eruptions of Vesuvius in 1906. Although reportedly rare<sup>2,3</sup> in subsequent volcanic eruptions, large visible atmospheric shock waves have accompanied explosive activity of Ngauruhoe, an andesite volcano in New Zealand, in 1954 (ref. 4), 1974 (ref. 5) and 1975.

During a series of seven highly explosive eruptions on the afternoon of February 19, 1975, observational and photographic records of eruption sequences were obtained, the most complete being of the largest explosion at 1810 NZDT which accompanied a volcanic earthquake of magnitude *M<sub>L</sub>* 3.4 (J. H. Latter, personal communication). Observations were made from both Mangatepopo Track and Chateau Observatory, respectively 3.4 km and 9.2 km from, and 1,110 m and 1,170 m below, the 100-m deep funnel-shaped summit crater. Each eruption was an isolated event following a 20–60-min period during which ash emission and volcano-seismic activity declined to very low levels. Explosion initiation appeared instantaneous, heralded by a large atmospheric shock wave clearly visible as a luminous arc expanding very rapidly through thin cloud, steam and clear air to several hundred metres above the crater. Attempts to photograph the shock waves were unsuccessful. Each shock wave was closely followed by the cannon-like, high-velocity projection above the crater of a dense slug of highly compressed gas and solid ejecta. Apparently due to vent shape the eruption slug formed three expanding sub-cylindrical coalescing plumes with rounded outlines and slightly pointed tops (Fig. 1a), when 200 m above the crater rim. The first photograph of the explosion was taken at this instant, between 0.5 and 1.0 s after observation of the shock wave. Figure 1b, taken by another observer a fraction of a second after Fig. 1a, records development of a sub-spherical hollow 'condensation cloud', surrounding and partly obscuring the expanding eruption slug. The diameter of the condensation cloud at this moment was ~500 m, although it extended a greater distance above the crater than down the slopes of the volcano (by ~1.8:1). Figure 1c, taken ~1 s later by a third observer, records disappearance of the condensation cloud, and outward expansion of the eruption slug to envelop the summit, while large blocks (up to 20 m across) were projected through it. Eight-millimetre cine film (18 frames s<sup>-1</sup>) taken of the explosion between photographs 1b and c, records the base of the condensation cloud 170 m above the crater (first frame), with its top extending into atmospheric cloud 580 m above the crater. The base of the condensation cloud travelled upwards at about 190 m s<sup>-1</sup> to reach 220 m above the crater

in the sixth frame of the film, before disappearing entirely in the seventh frame, exposed  $\sim 0.4$  s after the first.

The audible shock wave reached the Mangatepopo observation point as a very sharp and intensely loud 'crack' arriving 10.6 s after observation of the visible shock wave (G. T. Hancox, personal communication). This is equal within limits of error to the theoretical sound travel time of 10.58 s (assuming a sound velocity of  $338 \text{ m s}^{-1}$  in still air at  $10^\circ\text{C}$ ).

The atmospheric shock waves from each explosion were recorded as air-ground coupled waves at the Chateau seismograph 8.6 km from the crater. Air shock waves were also recorded on a nearby barograph. Each explosive pulse (up to

**Fig. 1** Sequential photographs of the 1810 NZDT eruption, February 19, 1975, taken by three observers reacting to the appearance of the preceding shock wave. *a*, Eruption slug projected above crater; *b*, expanding eruption slug surrounded by 'condensation cloud'; *c*, disappearance of condensation cloud. Photographs from Mangatepopo Track by G. T. Hancox, D. M. McVicker, and R. Foley.

$2.5 \times 10^2 \text{ Pa}$  above ambient in the 1810 eruption) was accompanied by a lesser fall (to  $1.5 \times 10^2 \text{ Pa}$  below ambient) in the following rarefaction phase. The explosions were heard more than 80 km from the volcano.

Short lived condensation clouds similar to those which formed at Ngauruhoe accompany nuclear explosions, an example being particularly clearly illustrated in photographs of the 1946 Bikini underwater explosion<sup>6,7</sup>. Formation of the cloud is due to rapid condensation of atmospheric water vapour in the adiabatically cooled rarefaction phase which is developed behind the positive overpressure phase of the shock wave. Subsequent re-evaporation and disappearance of the cloud occurs as atmospheric pressure returns to ambient (and temperature to slightly above ambient) behind the rarefaction phase<sup>6</sup>. The development of such condensation clouds does not appear to have been previously recorded in volcanic explosions. They were not recognised by scientific observers during the Ngauruhoe eruptions, and their existence was only realised after study of the photographs.

The shape of the 1810 NZDT condensation cloud (Fig. 1*b*) indicates that the initial near-planar shock wave within the vent had diffracted around the crater rim to produce a subspherical blast wave. The departure from sphericity of the cloud also suggests that if the shock moving down the cone had slowed to sonic speed (as seems likely from crater geometry and the measured sound travel time) the shock velocity directly above the crater was at least 1.8 times greater at Mach number  $M = 1.8$ , or  $\sim 600 \text{ m s}^{-1}$ .

An estimation of the initial velocity of the 1810 NZDT ejecta slug is hindered by lack of accurate timing of the first photographs, the limits of 0.5–1.0 s after explosion initiation indicating an average ejecta slug velocity ranging between 300 and  $600 \text{ m s}^{-1}$  over the first 300 m. Several methods of determining initial ballistic ejecta velocities from maximum range within the atmosphere have been developed, most recently by Wilson<sup>8</sup> who allowed for an increased drag coefficient ( $C_d$ ) at high Mach numbers. During the Ngauruhoe eruptions, a 0.8 m diameter lava block of density  $2.5 \text{ g cm}^{-3}$  was thrown 2.8 km, landing 980 m below the vent. Assuming a horizontal range of 2.5 km, a minimum initial velocity approaching  $400 \text{ m s}^{-1}$  is interpolated from Wilson's tables. That this is of the correct order may be indicated by the relationship from one-dimensional shock tube theory<sup>9</sup>

$$U = \frac{u_p}{2-2\mu^2} + \left( c^2 + \frac{1}{4} \left( \frac{u_p}{1-\mu^2} \right)^2 \right)^{1/2}$$

where  $U$  = shock velocity,  $u_p$  = piston velocity,  $c$  is velocity of sound, and  $\mu^2 = 1/6$  for air. A minimum initial Ngauruhoe shock velocity of  $600 \text{ m s}^{-1}$  (as suggested by condensation cloud shape) would be associated with a piston (that is, ejecta slug) minimum velocity of about  $340 \text{ m s}^{-1}$ . Similar velocities ( $> 330 \text{ m s}^{-1}$ ) have been observed for venting gases and ejecta in the Sedan underground thermonuclear explosion<sup>10</sup>, and considerably higher velocities ( $600\text{--}660 \text{ m s}^{-1}$ ) have been calculated for ejecta from explosive eruptions of Arenal, a volcano in Costa Rica<sup>8,11</sup>.

For cannon-like volcanic explosions, McBirney<sup>12</sup> has derived the equation  $P = 0.0125v^2$ , where  $P$  is the explosion pressure (atm) and  $v$  is ejecta velocity ( $\text{m s}^{-1}$ ). Assuming an initial ejecta velocity of  $400 \text{ m s}^{-1}$ , a minimum explosion pressure of  $2 \times 10^8 \text{ Pa}$  is calculated for Ngauruhoe. McBirney also deduces that such high pressures cannot be generated by the exsolution of volatiles from magmas of normal water content, but, instead, are caused by the rapid heating of confined meteoric water to near magmatic temperatures. This model it appears can be applied to Ngauruhoe, where a lava column rising within the volcano may rapidly heat pockets of meteoric water confined beneath the solid lava of an earlier formed plug<sup>5</sup>. High pressures develop until the mechanical

strength of the confining rocks is exceeded, and catastrophic failure occurs. Intense steam explosions result, with mechanism perhaps similar to that envisaged by Bennet<sup>13</sup>. At Ngauruhoe, the almost instantaneous release of pressures apparently  $> 2 \times 10^8$  Pa, at supersonic velocities, is clearly adequate to generate large visible shock fronts above the volcano.

I thank many other observers for photographs and descriptions, and G. R. Fowles, J. Healy, and J. H. Latter for discussions and advice.

## Temperature limits on the early Archaean ocean from oxygen isotope variations in the Isua supracrustal sequence, West Greenland

FROM a reconnaissance survey of the oxygen isotope composition of a sequence of metamorphosed sedimentary rock units at Isua, West Greenland, it is possible to set wide temperature limits of  $\sim 0$ – $146^\circ\text{C}$  on the early Archaean ocean.

The study area, part of the Greenland Archaean terrain, is 150 km north-east of Godthaab. The Isua supracrustal sequence, which consists of conglomerate, quartzite, acid metavolcanics, garnet-staurolite schist, banded iron formation, and laminated chert and carbonate interlayered with mafic flows or sills, may have been deposited in shallow water<sup>1</sup>. This sequence is enclosed by gneisses (Fig. 1) that range in composition from granodiorite to granite, and both the supracrustal sequence and gneissic terrain have been metamorphosed to amphibolite facies. A Pb–Pb age for the supracrustal sequence of  $3,760 \pm 70$  Myr has been determined by Moorbath *et al.*<sup>2</sup> from whole rock and from mineral separates of the banded iron-formation while an age of  $3,700 \pm 100$  Myr has been reported<sup>3</sup> for the gneissic terrain.

Oxygen isotope analyses were performed on laminated and massive cherts and on quartz separates from banded iron formations. Oxygen was liberated from 10–20-mg samples by bromine pentafluoride and converted to  $\text{CO}_2$  for mass spectrometric analysis<sup>4</sup>. Analyses were performed on a 15-cm,  $60^\circ$  sector mass spectrometer with a double inlet and a double collector.

The  $\delta^{18}\text{O}_{\text{SMOW}}$  values<sup>5</sup> for samples from three areas at Isua are presented in Table 1. Area one is the main iron formation occurrence at Isua<sup>2,6</sup>.  $\delta$ -values of laminated and massive chert units range from  $+16.1$ – $+20.3\text{‰}$ , the latter being the largest  $\delta$ -value reported for a precipitated Archaean siliceous sediment. The massive chert units in the area of the main iron-formation occurrence at Isua seem to have undergone limited rehomogenisation; therefore, the ratios may closely approximate the initial ratio of these units. Quartz separates from the banded iron formations in Area One range from  $+12.6$ – $+15.9\text{‰}$ , showing a probable re-equilibration of the quartz with magnetite during metamorphism. In comparison, as a result of meta-

morphic effects, cherts and quartz separates from Areas Two and Three are depleted in  $^{18}\text{O}$  as much as  $10.3\text{‰}$  compared to the maximum value found in sample 4-27/8-74 of Area One.

To interpret the data in Table 1, we have made four assumptions concerning the early Archaean ocean. First, the hydrosphere and atmosphere derived from volcanic emissions during the initial degassing of the earth as suggested by Fanale<sup>7</sup>. The water outgassed during this process should have a maximum  $\delta$ -value of approximately  $+6\text{‰}$ , as a result of high temperature equilibrium with igneous material. Second, oceanic water was cycled through parts of the oceanic crust allowing for isotopic exchange reactions with igneous material at high temperatures. Third, the  $\delta$ -values and environmental conditions of the early Archaean ocean are reflected in the  $\delta$ -value of the precipitated sediment, and are preserved in the rock units having the highest reported  $\delta^{18}\text{O}$  values. Finally, the mass of the Archaean ocean and the surface area of the earth, including the hydrosphere, were comparable to present day values.

Although the Isua cherts could have been precipitated under a number of different sets of conditions and still produce the same  $\delta$ -values, some realistic constraints may be placed on the palaeotemperature of the early Archaean ocean. A minimum temperature of approximately  $0^\circ\text{C}$  can be established for the Archaean ocean. The approximate lower limit is  $0^\circ\text{C}$ , since water must remain in a liquid state for precipitation of sediments. Different maximum temperatures can be achieved by assuming different initial  $\delta$ -values for the ocean. An upper temperature limit may be determined from the chert–water fractionation equation<sup>8</sup>

$$\Delta_{\text{CW}} = \frac{3.09 \times 10^6}{T^2} - 3.29$$

In the following, two different initial oceanic ratios are considered.

First, the Archaean ocean is assumed to have a  $\delta$ -value of

**Table 1** Oxygen isotope composition of chert and quartz from banded iron formations in the Isua Supracrustal belt

Sample	$\delta^{18}\text{O}_{\text{SMOW}}$	Remarks

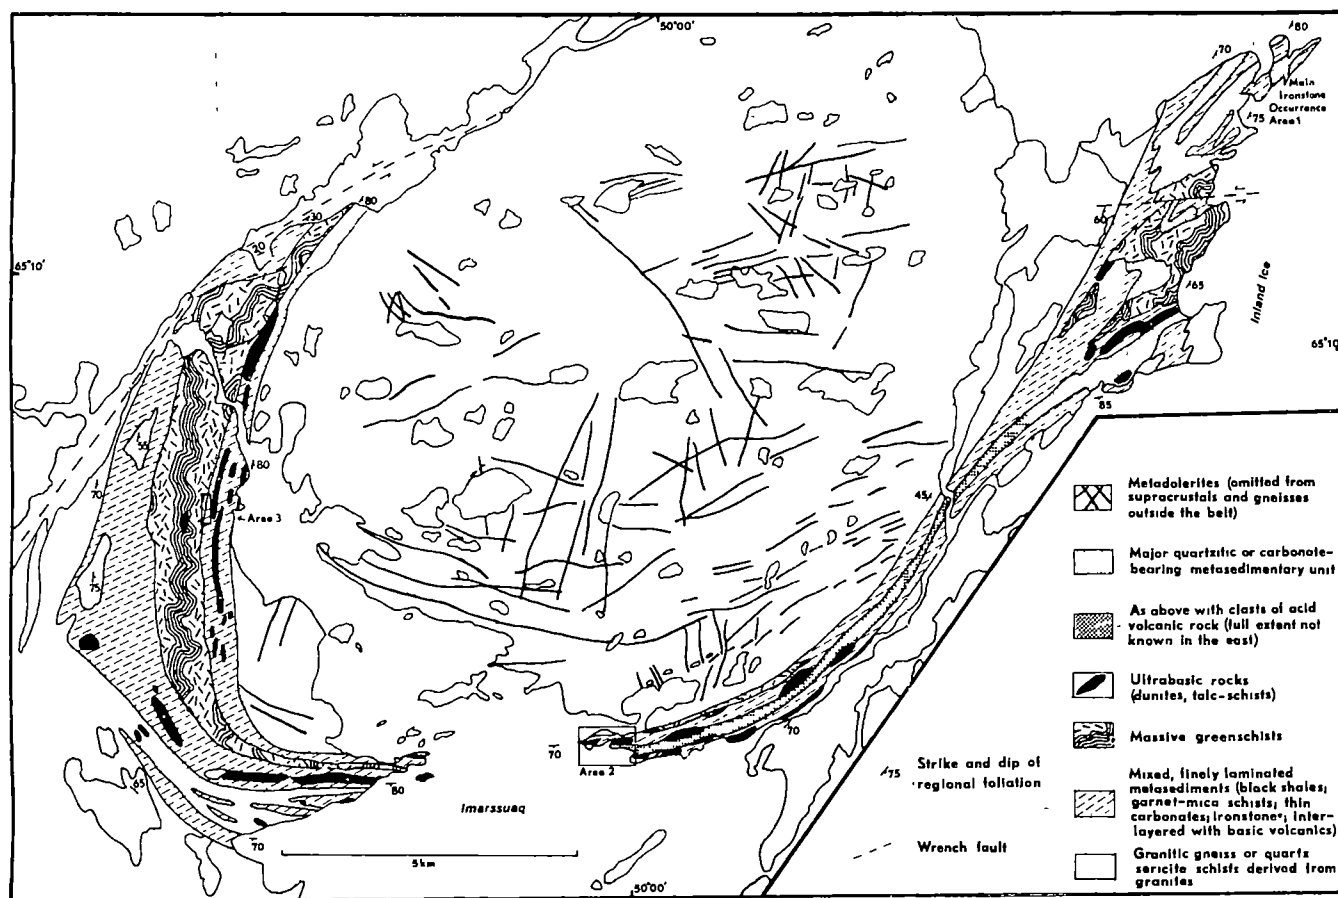

Fig. 1 Generalised geological map of the Isua supracrustal belt, West Greenland. Modified after Bridgwater and Fyfe<sup>6</sup>.

+6‰, the maximum for volcanic water in equilibrium with basalt at high temperatures. Isotopic fractionation between the Archaean ocean and the Isua chert with the maximum  $\delta^{18}\text{O}$  value (+20.3‰) is 14.3‰. This value is a minimum fractionation, and therefore, the corresponding temperature of 146 °C from the fractionation equation is an absolute maximum for the Archaean ocean. At this temperature, the partial pressure of  $\text{H}_2\text{O}$  in the atmosphere would be 4.65 atm; and 1.62% of the water in the present ocean would be required to produce this pressure.

In the second case, the  $\delta$ -value of the ocean is assumed to be 0‰, a value which has remained invariant with time. In these conditions, the ocean temperature would be ~ 89 °C and the partial pressure of water in the atmosphere equivalent to about 0.25% of the mass of the present ocean. Neither case 1 nor case 2 places any unreasonable mass deficiencies on the early Archaean ocean.

Another way (case 3) of achieving the observed  $\delta$ -values is for the Archaean ocean to have had the same temperature as now but with a  $\delta$ -value of -14‰. This assumes that the oceanic

Fig. 2  $\delta^{18}\text{O}$  variations in chert-bearing units as a function of age. Cretaceous cherts, Degens and Epstein (1962); Precambrian units except Isua cherts, ref. 9; Isua cherts, this study

isotopic composition through time has paralleled the maximum values of the chert data of Perry and Tan<sup>9</sup>, but has been displaced by  $-34\%$ .

Irrespective of the initial ocean  $\delta$ -value, processes affecting the oceanic system have occurred, allowing the establishment of the present day value of  $0\%$ . If the early ocean had a  $\delta$ -value of  $+6\%$  as assumed in case 1, the most important mechanism lowering the oceanic  $\delta$ -value would be large scale, low temperature sedimentary processes. Low temperature sedimentation would allow for preferential fractionation of  $^{18}\text{O}$  to the sediment, which in turn would deplete the oceans. In a hot or warm Archaean ocean (case 1 and 2) the importance of sedimentary processes in controlling  $\delta^{18}\text{O}$  of the ocean would be enhanced relative to other processes. To maintain the ocean at  $0\%$  since the early Archaean as in case 2, long term buffering of the oceans by basic rocks would be necessary<sup>10</sup>. The only process that would account for a rise in the  $\delta$ -value of the ocean for  $-14$  to  $0\%$  would be the active interaction of ocean water and igneous rock reservoirs at high temperatures through some type of cycling process<sup>11</sup>.

Figure 2 is a plot of age against  $\delta^{18}\text{O}$  of the Isua cherts and younger metamorphosed chert units showing an apparent decrease in  $^{18}\text{O}$  with increasing age to approximately 2,600 Myr. There is a constancy in the apparent maximum  $\delta$ -value of the Archaean chert bearing units. The change in slope at  $\sim 2,600$  Myr may reflect a variation in oceanic temperature coupled with changes in the mechanism which controlled the  $\delta^{18}\text{O}$ . These changes may have arisen from variations in the interactions between the oceans and the upper mantle. Evidence has been presented by Veizer<sup>12</sup> from  $^{87}\text{Sr}$  data implying a decrease in the amount of water cycled through crustal igneous reservoirs and/or increased sedimentation. The time at which the change of slope occurs is sensitive to small variations in the maximum value of  $\delta^{18}\text{O}$ . A further study of the Isua area is under way to confirm the range of  $\delta$ -values of the Isua cherts thus allowing for further and more thorough interpretation.

We thank Dr K. Ellitsgaard-Rasmussen, and P. Cloud for making it possible to sample the rocks at Isua, and J. H. Allaart and V. R. McGregor for help in the field. This research was supported by the NSF and by Northern Illinois University and made possible through the cooperation of the Geological Survey of Greenland.

## Multiple sources of pumice in the Aegean

QUATERNARY pumice has been produced in at least ten volcanic eruptions in the southern Aegean, from volcanoes on the islands of Melos, Santorini, and various of the Dodecanese. This multiplicity of sources has not been generally recognised before, but it should be taken into account in submarine core sampling.

Fig. 1 Plots of chemical analyses of Quaternary pumice from various volcanoes in the Aegean. A,  $\text{Na}_2\text{O} + \text{K}_2\text{O}$ ; F, total iron as  $\text{FeO}$ ; M,  $\text{MgO}$ . •, 1470 BC Santorini, □, pumice 'G', Nisyros, ■, pumice 'A', Nisyros; ▽, pumice 'C', Yali; ▼, pumice 'D', Yali, ×, plateau pumice, Kos, Kalymnos, Pserimos and Telos; ○, Kefalos pumice, Kos.

The pumice on Melos occurs in a large ring in the south of the island. The ring, which is built up of repeated units of pyroclastic surge deposits, shows only slight erosion and therefore probably dates from the late Quaternary.

On Santorini, seven layers of pumice occur in the caldera walls at Kap Alai<sup>1</sup>. The eruptions which produced the two largest deposits, consisting of air-fall pumice and ashes, and pyroclastic flows, have been dated at 18000 BC and 1470 BC<sup>2</sup>. The older pumice deposit is locally  $>50$  m thick. Isopach maps<sup>3</sup> of the products of the younger eruption suggest that the 0.01  $T_{\text{max}}$  isopach, that is the 5.5 cm isopach, must cover several thousand  $\text{km}^2$ , and the eruption was thus of plinian type<sup>4</sup>. The isopachs are extended along a dispersal axis south-east of Santorini, and ash from this eruption has been identified from deep-sea cores from this area<sup>5</sup>.

In the Dodecanese, the products of eight pumice eruptions from three island volcanoes can be distinguished. Several pyroclastic deposits occur on Kos, and the least altered of these, here called the Kefalos deposit, occurs around the rhyolite dome of Mt Xenia. The deposit consists of repeated thin pyroclastic surge and non-welded ignimbrite flow units and covers  $>9 \text{ km}^2$ . It is overlain by the products of a much larger eruption, including pyroclastic surge deposits, ignimbrites, and associated mud-flows. This plateau deposit covers the central and western parts of Kos and is also found on the islands of Kalymnos, Pserimos and Telos, respectively 18 km north, 8 km north, and 50 km south of Kos<sup>6</sup>. On these islands the plateau deposit is confined to valleys and bays facing Kos. The products of this eruption must cover  $>2,500 \text{ km}^2$ .

On Yali, 2 km south of Kos, there are two pumice fall deposits. The older one, 'D', is  $>180$  m thick, built up of reversely-graded units dipping steeply north-east, and is possibly the remnant of a pumice ring. This is covered by a second fall deposit, 'C', which is 3 m thick. Between these two, an horizon of marine shells occurs at 170 m above sea level, showing that considerable vertical movements have taken place.

**Table 1** Percentage weights of phenocryst minerals in the Aegean pumices and refractive indices (r.i.) of glasses

	Phenocrysts (weight %)	Quartz (weight %)	Feldspar (weight %)	r.i.	Biotite (weight %)	Magnetite (weight %)	O'px. (weight %)	C'px (weight %)	Refractive index of glass
Santorini (1470 BC)	10		82	1.553			16	2	1.509
Nisyros (pumice 'G')	10		80	1.553		2	17	1	1.492
Nisyros (pumice 'A')	24		83	1.548		3	13	1	1.497
Yali (pumice 'C')	2	✓	✓	1.546					1.492
Yali (pumice 'D')	1	✓					✓		1.497
Plateau pumice, Kos	26	71	10	1.540	18	1			1.492
Kefalos pumice, Kos	8	98	2	1.540					1.501
Melos	4	92	5	1.548	2	1			1.492

✓, Present in small quantities; not measured.

Pumice from four eruptions has been preserved on Nisyros island, ~2 km south of Yali. The oldest is a pumice fall deposit exposed near the base of a cliff section within the caldera. The second fall deposit, 'G', which is rich in lithic fragments including metamorphosed limestones and plutonic rocks, is preserved mainly in the valleys on the south-west side of the island. The youngest deposit, 'A', is a pumice fall more than 20 m thick on the north-east side of the island. Pyroclastic flows which are exposed above 'G' along the north-east coastal section, seem to be the products of a fourth eruption. Fall deposits 'A' and 'G' are of plinian type.

**Fig. 2** Plots of CaO and Na<sub>2</sub>O+K<sub>2</sub>O against weight % SiO<sub>2</sub> for the same analysed samples as in Fig. 1; analyses recalculated to 100% water-free. The analyses cover the range dacite–rhyodacite–rhyolite–leucorhyolite.

The steep slopes and small size of Yali and Nisyros make it difficult to construct isopach maps of the pumice deposits. From the considerable thickness of deposits 'D' and 'A' it seems probable, however, that ashes from these islands, as well as from Santorini and Kos, should be widely found in cores from the south-east Aegean.

Major element X-ray fluorescence analyses have been made on pumice from the main eruptions to characterise these deposits. The plots of these analyses (Figs 1 and 2) illustrate the principle chemical differences. The refractive index of the glass, and the percentage and type of phenocryst minerals within the pumices have also been determined (Table 1) as an aid to the identification of the pumice from the various eruptions.

## Ocean rise-like basalts within the Galapagos Archipelago

THE Galapagos Archipelago, Iceland, and other oceanic islands, have been interpreted as surface manifestations of mantle plumes<sup>1–3</sup>. A key element of this model of island development centres on the petrological and geochemical contrasts between suites of lavas erupted from the proposed mantle plumes and at oceanic rises<sup>1–3</sup>. But the recognition of basalts of ocean rise composition on Iceland has prompted modification of models of petrological processes in mantle plumes<sup>4,5</sup>. We know of only one other reported occurrence of ocean rise-like basalts erupted on islands of proposed plume origin: flows in the Pololu Series on the Island of Hawaii<sup>6</sup>.

Here we report a newly discovered occurrence of ocean rise-type basalts erupted on Santiago Island, Galapagos. The presence of these distinctive rocks is an important factor in interpreting the possible roles of mantle plume activity or other tectonic forces in the development of the Galapagos Archipelago.

Ocean rise basalts are typified by consistently low abundances of incompatible elements (such as, K<sub>2</sub>O, TiO<sub>2</sub>, and P<sub>2</sub>O<sub>5</sub>), (refs 3, 7 and 8). Most ocean rise basalts are devoid of clinopyroxene phenocrysts, but commonly contain olivine and/or plagioclase phenocrysts<sup>3,8</sup>. Some pyroxene phenocrysts have, however, been observed in samples dredged from the rift valley of the Galapagos Rise<sup>2,9</sup>. The compositional variation among ocean rise basalts, though quite small, has been attributed to fractional crystallisation<sup>7,9</sup>, to varying degrees and depths of partial melting<sup>3</sup>, and to differences in the compositions of parental material<sup>10</sup>.

The same mechanisms have also been proposed as the source of more pronounced differences between ocean rise basalts and plume-derived lavas<sup>3,11,12</sup>. The consistently low abundances of incompatible elements in ocean rise basalts contrast with the much greater compositional and petrographic variation and generally higher abundances of these elements in lavas erupted on oceanic islands of proposed plume origin.

†Total H<sub>2</sub>O loss on ignition at 500 °C.

Petrographically and compositionally, the low-K<sub>2</sub>O lavas erupted on Santiago are essentially identical to olivine tholeiites sampled from the East Pacific Rise, the Galapagos Rift and other active spreading centres (Table 1 and Fig. 1). The Santiago lavas contain up to 10% phenocrysts of olivine and plagioclase in a matrix of plagioclase laths, clinopyroxene, olivine and opaques. No pyroxene phenocrysts were observed in the eight samples we examined.

The ocean rise-type lavas from Santiago are characterised by much lower abundances of the incompatible elements and higher MgO, CaO and Al<sub>2</sub>O<sub>3</sub> than either average Galapagos Island tholeiite<sup>13</sup> or the more alkalic lavas also found on Santiago (Table 1). Variation diagrams of selected depleted elements against the ratio FeO\*/MgO (ref. 14) show that the low-K<sub>2</sub>O lavas are clearly disjunct from suites of other Galapagos Island rocks (Fig. 1).

Several petrological features of the ocean rise-type basalts on Santiago indicate that they are the product of a distinct process taking place beneath the central area of the Galapagos platform. The low-K<sub>2</sub>O lavas are younger than or coeval with the alkalic rocks which form the bulk of the exposed portion of Santiago. This is the reverse of the typical tholeiitic-alkalic lava sequential history of Hawaiian volcanoes<sup>15</sup>. Furthermore, it is unlikely that the ocean rise-type basalts are genetically related to the older or contemporaneously erupted alkalic lavas by any sort of crystal fractionation process<sup>3,10,16</sup>.

Structural features associated with the ocean rise-type lavas suggest that these petrological features are related to a relatively young phase of tectonic activity in the central and eastern portion of the Galapagos Archipelago. The low-K<sub>2</sub>O lavas on Santiago were erupted from fissures which are part of an easterly trending structural pattern of aligned vents, normal faults and fissures, and uplifted submarine lavas observed on seven islands in the central and eastern portion of the archipelago (Fig. 2)<sup>17</sup>. This structural pattern postdates the construction of the principal volcanoes forming Santiago, Santa Cruz and San Cristobal. On islands where the structural features can be dated, their ages are less than about 0.5 Myr. The ocean rise-type lavas on Santiago were erupted over the past several hundred thousand years and as recently as 1906.

The fault patterns and uplifted lavas record uplift and north-south distention in a zone extending eastward from the centre of the archipelago<sup>17</sup>. This zone straddles an east-west trending negative gravity anomaly<sup>18</sup>. Although scanty data preclude an unambiguous explanation of the

gravity low, it has been interpreted as the result of an elongate east-west curtain of mantle upwelling beneath the archipelago<sup>18,19</sup>. Such a zone of upwelling would parallel the zone of active seafloor spreading at the Galapagos Rift 150 km to the north (Fig. 2)<sup>20</sup>. The close spatial and temporal relationship among the subaerially erupted, ocean rise-type basalts on Santiago, the zone of uplift and north-south distention, and the negative gravity anomaly, suggest there has been a relatively recent (0.5 Myr BP to present) period of mantle upwelling beneath the central and eastern portion of the Galapagos Archipelago. Perhaps these features signal incipient rifting of the Galapagos Platform

by ocean rise-type processes in a fashion similar to the splitting of the ancestral Carnegie Ridge (see ref. 21).

The recent petrological-tectonic history of the central Galapagos could also be interpreted using the currently popular model of mantle plumes. Using a mantle plume hypothesis analogous to the model proposed for Iceland and the Reykjanes Ridge by Sigvaldason *et al.*<sup>4</sup>, the ocean rise-type lavas could be derived from source material progressively depleted during lateral plume flow eastwards from a hot spot at present centred beneath Fernandina Volcano. Other models would derive both low-K<sub>2</sub>O lavas and typical oceanic island basalts from different regions within the column of the upwelling plume<sup>5</sup>.

We feel, however, that 'hot spot' and mantle plume models of island development contribute little to our understanding of the history of the Galapagos Archipelago. Clearly, the available geological and geochemical data are insufficient to devise a realistic, unambiguous petrological-tectonic model for the Galapagos region. As in the case of Iceland<sup>22</sup> the Galapagos Islands seem to have had a complex history influenced by several distinct but possibly superimposed petrological and tectonic regimes.

## Geomagnetic excursion from Imuruk Lake, Alaska

UNGLACIATED Arctic lake sediments probably offer the best opportunity for correct stratigraphic correlation and radiocarbon dating of brief geomagnetic events.

We possess a series of lake sediment cores from Imuruk Lake, Seward Peninsula, Alaska, which represent a time interval well beyond the range of radiocarbon dating<sup>1</sup>. Pollen analysis of Arctic Alaskan lake sediments can be used to identify glacial and non-glacial episodes with considerable precision<sup>2</sup> and the pollen record from one Imuruk Lake core suggests that at least one, and perhaps two, complete glacial cycles are included<sup>3</sup>. Our suite of cores thus offers an opportunity to study the history of palaeo-magnetic events over a time interval of perhaps 200,000 yr. We report here the discovery of the Imuruk geomagnetic excursion some 18,000 yr b.p.

Fig. 1 Sampling intervals and geomagnetic excursion interval in Imuruk Lake core IV. N, Normal polarity samples; E, geomagnetic excursion samples. Radiocarbon dates as in Table 1.

**Table 1** Radiocarbon dates on Imuruk Lake core IV

5-12 cm (I-3631)	10,700 ± 150 yr b.p.
96-115 cm (I-3632)	11,910 ± 180 yr b.p.
172-184 cm (I-3662)	25,850 ± 2,400 yr b.p.

The discovery was made with Imuruk Lake Core IV (coordinates 65°37' N, 163°8' W) collected in August, 1960 (ref. 1). The core was stored in the Dural sample tubes with which it was taken until 1967, when it was extruded and examined using radiocarbon dating and pollen analysis<sup>3</sup>. Since then, the core has been wrapped in Saran film and stored at 4 °C. Core IV is short (2.5 m), but it includes pollen zones, J, K, and L, representing glacial and early postglacial time<sup>1-3</sup>. Three radiocarbon dates (Table 1) show that the core spans the interval from before 25,000 yr b.p. to about 10,000 yr b.p. This interval spans the estimated ages of a number of geomagnetic excursions, noticeable among them that from Lake Biwa at 18,000 yr b.p. (ref. 4). We found the dating of the Biwa Event particularly interesting because it is synchronous with the last glacial maximum. Accordingly, we chose for our reconnaissance samples the interval of Imuruk core IV in which the sediments of 18,000 yr b.p. must lie.

We removed twelve core samples from the upper 160 cm of Imuruk Core IV (Fig. 1). The cores were measured using a Schonstedt SSM-1A spinner magnetometer. Following the measurement of the natural remanent magnetisation (NRM), the cores were subjected to successive stages of alternating field demagnetisation (a.f.d.) using a Schonstedt GSD-1 demagnetising unit. The total moments of the NRM averaged  $5.0 \times 10^{-3}$  gauss cm<sup>3</sup>, with individual core volumes of 10 cm<sup>3</sup>. Ten cores had NRM inclinations averaging 45° and may be considered of normal polarity. Two adjacent cores at 132-135 cm and 136-139 cm (Fig. 1) had NRM inclinations averaging 13°. All of the NRM moments had a similar magnitude suggesting that the NRMs of the two cores with low inclination record a sudden excursion of the geomagnetic field.

We tested the stability of NRM of the samples by demagnetising them in an alternating field to a peak of 400 oersted, in stages of 100 oersted. After a.f.d. to 400 oersted all of the samples showed the same rate of decrease of residual moment to about 25% of their initial values, which suggests that their magnetic mineralogy is uniform (Fig. 2, Table 2). After demagnetisation, the residual inclinations of the samples with normal polarity averaged 48°, a few degrees more than their average NRM inclination. The two samples with low NRM inclinations, however, had residual magnetisations nearly horizontal, 13° less than their average NRM inclination. This indicates that the stable NRM moments in the samples are free of

**Fig. 2** Alternating field demagnetisation results. ●, Samples with normal (positive) magnetic inclinations; ○, samples with nearly horizontal (excursion) inclinations.  $J/J_0$  is the ratio of NRM to the residual moment after a.f.d.

a consistent bedding plane error, and that there was a change of geomagnetic inclination of approximately 50°. The magnitude of this change is close to the 55° change recorded by Yaskawa *et al.*<sup>4</sup> from the Lake Biwa (35°13' N, 136°01' E) results. This change was sufficiently abrupt to have occurred between adjacent samples (Fig. 1), suggesting that the decrease in inclination was very rapid, a circumstance which may be tested by investigating the rate at which the Imuruk lake sediments accumulated. It is most unlikely that any of the core samples acquired their NRM long after initial deposition. (Verosub<sup>5</sup> reports

**Table 2** NRM (a) and 400-oersted (b) residual magnetisation results\* for seven samples of Imuruk Lake core IV

\*The results are plotted in Figure 2. The coring tube was not oriented for azimuth and the declinations are not correct in geographic coordinates

finding stable NRM in lake sediments acquired within 5 years of deposition.) The conditions in which sediment collects at Imuruk Lake<sup>1</sup> preclude the possibility of small scale folding of the deposit similar to that reported by Verosub<sup>5</sup> for a glacial lake in Massachusetts which locally reproduced the effect of a geomagnetic excursion. Furthermore, the part of the Seward Peninsula containing Imuruk Lake was free of ice during the Wisconsin glaciation<sup>9</sup>. We conclude that the samples record the orientation of the local geomagnetic field at the time of deposition, and that the low inclination of the two cores represents a real geomagnetic excursion. We have not yet identified the magnetic minerals in the core, but the data are consistent with detrital magnetite contributing about 50% of the NRM, as has been noted in other Recent lake sediments<sup>6-8</sup>.

The average inclination of the stable NRM moments ( $48^\circ$ ) in the majority of the samples is about  $27^\circ$  less than that expected at the latitude of  $65^\circ\text{N}$ , assuming a geocentric dipole source for the main geomagnetic field. We can reduce the discrepancy to  $22^\circ$  because of a  $5^\circ$  tilt of the lake bed to the south about 10,000 yr b.p.<sup>9</sup>. The inclination of the stable NRM of the majority of the Lake Biwa samples<sup>4</sup> during the equivalent time interval (11,000–24,000 yr b.p.) averages about  $48^\circ$ ,  $5^\circ$  less than expected for a geocentric dipole at  $35^\circ\text{N}$ . The present-day geomagnetic inclination in the Seward Peninsula region is  $75^\circ$  (ref. 10), and there is no evidence of a localised anomalous vertical intensity of  $-11,000\text{ }\gamma$  near Imuruk Lake, which would be required systematically to diminish by  $20^\circ$  the local geomagnetic inclination during a normal polarity epoch. The low value we observe for the stable NRM inclination may be the result of our small sample, or there may have been a low geomagnetic inclination in the North Pacific region during the Wisconsin Glaciation. The presence of a geomagnetic excursion involving a change in inclination of  $50^\circ$  is, however, clear.

If we assume that the accumulation of sediment between the radiocarbon dates bounding the event (Table 1) is linear, the sedimentation rate during the period of the event is about 1 cm every 193 yr. We can identify the approximate position of the polarity event in other cores using pollen stratigraphy, because the event lies nearly in the middle of pollen sub-zone  $J_3$  (refs 1–3). In Imuruk Core I, taken about one mile from Core IV, the middle of  $J_3$  lies at a depth of 90 cm. This lies between the radiocarbon age of  $13,250 \pm 700$  yr b.p. at 50–60 cm, and more than 34,500 yr b.p. at 110–120 cm (ref. 7). Assuming a linear sedimentation rate between these ages, the minimum rate would be 7 cm every 300 yr. In Imuruk Core II, taken a mile from cores I and IV, the middle of sub-zone  $J_3$  lies at a depth of 60 cm and is bounded by radiocarbon ages of  $12,160 \pm 300$  yr b.p. at 5–10 cm, and more than 28,700 yr b.p. at 100–114 cm. Assuming a linear sedimentation rate gives a minimum rate of about 1 cm every 200 yr.

The interval of time spanning these pairs of dates includes both intervals of maximal glacial advance and of glacial retreat, so that some fluctuations in the rate at which sediments accumulated must be expected. The assumption of linearity in sedimentation rate cannot, therefore, be valid. Nonetheless the sediments enclosing the geomagnetic excursion in Core IV must have accumulated at a rate of 1 cm about every two or three centuries. At the onset and close of the excursion (Fig. 1) there was a change in the geomagnetic inclination of  $50^\circ$  within 1 cm of sediment (a time interval of 200–300 yr). The excursion persisted during the accumulation of 9 cm of sediment, a time interval of 1,800–2,700 yr.

Our closest estimate for the actual radiocarbon age of the excursion can be obtained from Fig. 3. Figure 3a describes the accumulation of sediments in Lake Biwa<sup>11,12</sup>, and shows an exponentially changing relationship of age

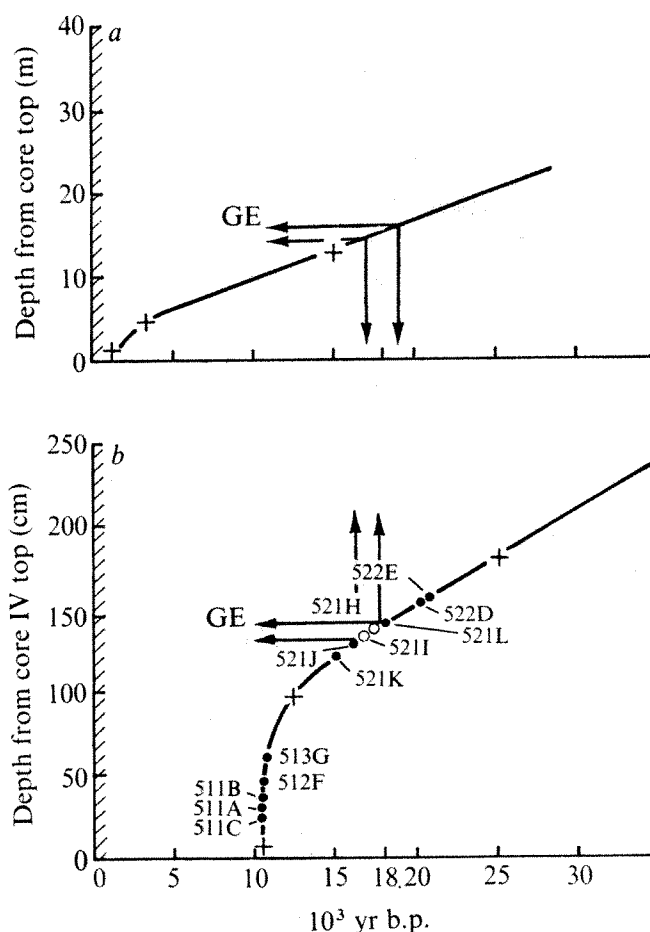

Fig. 3 Sediment accumulation and geomagnetic excursion interval at a, Lake Biwa<sup>9</sup> and b, Imuruk Lake. ●, Position of normal polarity samples; ○, geomagnetic excursion samples; crosses, radiocarbon dates; GE, geomagnetic excursion.

against depth as the sediments compact, eventually becoming linear.

Figure 3b is a similar diagram for Imuruk Lake Core IV, based on the radiocarbon dates given in Table 1. The steep age-against-depth relationship in the upper 100 cm of the core mainly reflects the truncation of the lake sediment by wave action in the shallow water of the contemporary lake<sup>9,13</sup>. The positions of the samples are indicated, and the age of the excursion is between 17,000 and 18,000 yr b.p.

It seems likely that much of the scatter in the ages of polarity events is a consequence of uncertainties in radiocarbon age determinations, or they could arise from linear extrapolation of age when the age-depth relationship is not linear. In the examples of Lakes Biwa and Imuruk, such a linear extrapolation in sediments near the top of the core would result in an underestimate of the age of the polarity event. We speculate that some of the polarity events reported for the 8,000–20,000 yr b.p. interval may be more correctly dated in the 17,000–19,000 yr b.p. interval.

It should be possible to detect the 18,000 yr b.p. geomagnetic excursion (and probably others) in equatorial sediments or igneous rocks where the normal geomagnetic inclinations are close to horizontal, even when cores are not oriented in the horizontal plane. This is because the excursion is accompanied by an apparent shift of the geomagnetic dipole axis by about  $30\text{--}35^\circ$ , and by an inclination change of  $50\text{--}55^\circ$ , which is somewhat different from the changes accompanying a geomagnetic polarity reversal. A geomagnetic reversal involves a symmetrical change of

inclination and declination, the inclination changing sign and the declination changing by  $180^\circ$ . It is not necessary to know the declination of a sample if the inclination change is approximately  $50^\circ$  at any latitude during an excursion.

P. Colbaugh undertook the pollen analyses of Core IV and R. Marino assisted with the sub-sampling of the Cores and the magnetometry. The work was supported by the NSF.

## Crystal structure of green rust formed by corrosion of cast iron

THE principal solid corrosion products of iron in water are magnetite and hydrated forms of ferric oxide, depending on the degree of oxidation. The occurrence of intermediate products, termed green rusts, was reported by Keller<sup>1</sup> in 1948, since when the formation and decomposition of these compounds, precipitated from aqueous solution by controlled oxidation of ferrous hydroxide, have been extensively studied<sup>2–5</sup>. It has been proposed<sup>2,3</sup> that specific anions are incorporated in the crystal structure of some green rusts, although no substantial evidence has been found to confirm this. A number of green rusts have been classified crystallographically<sup>3</sup> as follows: first, rhombohedral green rusts I (GRI) formed in  $\text{Cl}^-$ ,  $\text{SO}_4^{2-}$  and  $\text{Br}^-$  solutions and (second), hexagonal green rust II (GRII) formed only in  $\text{SO}_4^{2-}$  solutions by decomposition of GRI. The interrelationships between the various products involved in the oxidation of ferrous hydroxide have been summarised by Misawa *et al.*<sup>5</sup> In this paper a preliminary account is given of the crystal structure of a rhombohedral green rust formed by corrosion of iron which, although of

similar unit cell dimensions to GRI, differs structurally from those previously reported.

Preliminary corrosion experiments were conducted on cast iron in waters containing  $\text{NaCl}$ ,  $\text{K}_2\text{SO}_4$ ,  $\text{Na}_2\text{CO}_3$ , mixtures of these salts and  $\text{NaOH}$  under various degrees of aeration. Optical microscopy showed that the corrosion products contained varying amounts of  $\text{Fe}_3\text{O}_4$ ,  $\gamma\text{-FeOOH}$  and a green compound presumed to be a green rust. X-ray powder diffraction confirmed the presence of  $\text{Fe}_3\text{O}_4$  and  $\gamma\text{-FeOOH}$ , but

**Fig. 2** *a*, Transmission electron diffraction pattern of green rust and magnetite. *b*, Indexed diagram:  $\circ$ , green rust;  $\bullet$ ,  $\text{Fe}_3\text{O}_4$ . Indices for  $\text{Fe}_3\text{O}_4$  may be deduced by reference to Fig. 1.

additional diffraction lines could not be matched with published lines for GRI or GRII. The diffraction pattern for the green compound was found to be independent of the type and combination of anion present in solution and also found to be unaffected by the level of dissolved oxygen. An oxygenated solution of  $\text{Na}_2\text{CO}_3$  ( $\text{CO}_3^{2-} = 200$  p.p.m. by weight) proved to be a convenient medium for growth of the green compound with relatively small quantities of  $\text{Fe}_3\text{O}_4$  and  $\gamma\text{-FeOOH}$  to cause interference. Thirteen unassigned lines obtained in the X-ray powder spectrum for this corrosion scale may be indexed in the rhombohedral system as shown in Table 1. Unit cell dimensions calculated from these data are  $a_R = 7.5 \pm 0.26 \text{ \AA}$  and  $\alpha = 21.52 \pm 1.15^\circ$ ; equivalent hexagonal dimensions are  $a_0 = 3.181 \pm 0.04 \text{ \AA}$  and  $c_0 = 21.82 \pm 0.8 \text{ \AA}$ . X-ray diffraction lines, ascribed by Butler and Beynon<sup>6</sup> to a chloride green rust in studies of corrosion of mild steel in boiling salt solutions, are closely related to those shown in Table 1.

Scanning electron microscopy shows that the green compound comprises clusters of flat crystals with a well-formed hexagonal

Fig. 3 Scanning electron micrograph showing magnetite growth on hexagonal green rust crystals.

habit. Single crystals were extracted from the corrosion product and prepared for transmission electron microscopy by methods to be described elsewhere. Figure 1a shows a transmission electron micrograph of a single crystal of the green compound and Fig. 1b the corresponding selected area electron diffraction pattern with a superimposed ring pattern from gold used as an internal standard. Figure 1c shows the indexed diffraction pattern. The beam direction is  $[1\bar{1}\bar{1}]_R$ ; two planes of the set  $\{211\}_R$  and four planes of the set  $\{110\}_R$  are diffracting and have similar  $d$  spacings giving the inner group of six spots; the outer group comprises two further reflections from  $\{110\}_R$  and four from  $\{321\}_R$ . The habit plane of the crystal, which is normal to  $(\bar{1}\bar{1}\bar{1})_R$  is most closely represented as  $\{5\bar{6}\bar{6}\}_R$ , and is  $5^\circ 48'$  from the hexagonal basal plane,  $(0001) \equiv (111)_R$ .

Diffraction from certain crystals of the green compound shows a second pattern superimposed on the green rust pattern (Fig. 2a). This can be indexed (Fig. 2b) as magnetite, evidently growing on the surface of the green compound. The orientation relationship between the green compound and magnetite is  $[1\bar{1}\bar{1}]_R \parallel [1\bar{1}\bar{1}]_C$  and  $(5\bar{6}\bar{6})_R \parallel (1\bar{1}\bar{1})_C$ . Morphological evidence for an epitaxial growth of magnetite on the green compound is shown in Fig. 3, in which magnetite crystallites occur on opposite faces of the hexagonal crystals.

It is concluded that the green compound formed by corrosion of iron differs structurally from green rusts I and II produced by solution precipitation. The compound is remarkably stable, and has been found coexisting with  $\text{Fe}_3\text{O}_4$  and  $\gamma\text{-FeOOH}$  in highly oxidising conditions. It is believed that the compound has a significant role in the formation of conventional scales on ferrous surfaces in aqueous environments. Work is in hand on the chemical analysis of the compound.

## Organic complex radical anion salt metallic down to 30 mK

THE classical, but still recent, example of an organic metal, TTF-TCNQ, has been fully investigated and reviewed by two groups<sup>1,2</sup>. It has a room temperature electrical conductivity of  $\sim 10^3 \Omega^{-1} \text{ cm}^{-1}$  which increases on cooling to a maximum, with  $\sigma_m/\sigma_{RT} \sim 10$ -15, at  $\sim 58 \text{ K}$  (ref. 1), where it undergoes a metal-semiconductor transition. In 5 of 150 crystals,  $\sigma_m/\sigma_{RT} > 20$ -150 has been reported<sup>1</sup>. Recently<sup>3</sup> a congener HMTSF-TCNQ (hexamethylene tetraselenafulvalinium tetracyanoquinodimethanide) was reported to have  $\sigma_{RT} = 1,391$ -2,178  $\Omega^{-1} \text{ cm}^{-1}$  increasing to  $\sigma_m/\sigma_{RT} \sim 3.4$  at 75-45 K, when it decreases to  $\sigma/\sigma_{RT} = 0.3$  at 1.5 K. These organic substances showed no superconducting transition, in contrast with the inorganic polymer (SN)<sub>x</sub> which, while mostly behaving similarly<sup>4</sup>, also shows the onset of superconductivity at 0.26 K (ref. 5).

Here we report a new organic metal, the first organic complex ever to show a monotonic increase in conductivity on cooling from room temperature to 30 mK. The complex is

1,2-di(N-ethyl-4-pyridinium)ethylene<sup>2+</sup> (7,7,8,8-tetracyanoquinodimethane)<sub>4</sub><sup>2-</sup> which we abbreviate to (DEPE)<sup>2+</sup>(TCNQ)<sub>4</sub><sup>2-</sup>.

The complex, prepared in a similar manner to its semi-conducting congeners<sup>6</sup>, was grown as single crystals from acetonitrile, and the stoichiometry determined by micro-analysis and spectral examination in the visible region<sup>7</sup>. Semi-conducting and metallic forms of (DEPE)<sup>2+</sup>(TCNQ)<sub>4</sub><sup>2-</sup>, each with the same stoichiometry, were obtained. The conditions of preparation still remain to be determined completely.

Current and voltage probes were attached to opposite faces of the crystals, as shown in Fig. 1, with Acheson high conductivity silver paint as electrodes. A constant current was applied and the voltage drop measured by using a Keithley 640 electrometer. The electrode resistance was insignificantly small compared with the sample resistance throughout the temperature range studied.

In this communication we report the preliminary d.c. conductivity data on nine metallic single crystals (mean dimensions  $4 \times 2 \times 0.5 \text{ mm}$ ) isolated from two batches. The conductivities at 300 K of (DEPE)<sup>2+</sup>(TCNQ)<sub>4</sub><sup>2-</sup>, 150-2,200  $\Omega^{-1} \text{ cm}^{-1}$ , are among the highest known for any organic material. They may be compared with the value of  $\sim 0.26 \Omega^{-1} \text{ cm}^{-1}$  reported<sup>8</sup> for polycrystalline 1,2-di(N-methyl-4-pyridinium)ethylene<sup>2+</sup>(TCNQ)<sub>2</sub><sup>2-</sup>, a closely related complex. The conductivity increases monotonically on cooling from 340 K to 30 mK (Fig. 1) with  $\sigma_{30 \text{ mK}}/\sigma_{RT} = 3.7$ . In the range 50-340 K,  $\sigma/\sigma_{RT} = 23T^{-0.55}$  with a weaker dependence at lower temperatures. In this region, a transition to superconductivity was not observed.

**Fig. 1** The normalised electrical conductivity of  $(\text{DEPE})^{2+}-(\text{TCNQ})_4^{2-}$  as a function of temperature. Insets: *a*, the low temperature region expanded and *b*, the crystal with current and voltage probes attached.

The temperature exponent of  $-0.55$  is considerably less than the values of  $-2.33$  for  $\text{TTF-TCNQ}^{9,3}$ , and  $-2.39$  for  $\text{HMTSF-TCNQ}^3$ . Allender *et al.*<sup>10</sup> have analysed the Fröhlich fluctuation-induced charge density wave conductivity  $\sigma_F$  of a one-dimensional metal obtaining the result  $\sigma_F \propto [T_c/(T-T_c)]^{0.5}$ , which, while it does not fit  $\text{TTF-TCNQ}$ , would fit the present data if  $T_c \ll T$ . If this theory holds (see also Strässler and Toombs<sup>11</sup>), we shall need to understand why the electron-acoustic phonon interactions would be dominant for our material, while optical phonon interactions must be involved for  $\text{TTF-TCNQ}^{12}$ . It is also interesting that the  $\sigma/\sigma_{RT}$  against  $T$  plot for  $(\text{DEPE})^{2+}-(\text{TCNQ})_4^{2-}$  down to 100 K closely follows that for neodymium, where the conductivity is dominated by spin disorder scattering<sup>13</sup>.

The anisotropy of conductivity has still to be established. If it turned out to be two-dimensional, as is found in a related semiconductor<sup>6</sup>, rather than one-dimensional, this might explain the absence of a Peierl's transition. The difference between the metallic and semiconducting species may depend on crystal structure, defect state, or indeed on differences in degree of charge transfer in the surface<sup>14,15</sup> on which we are now working.

We thank Drs Susan F. J. Read, D. B. Thomas and Mr H. E. Walford of the SRC Rutherford Laboratory for help with the measurements below 4 K.

## Model reaction for biological reduction of nitrate involving $\text{Mo(III)/Mo(V)}$

WE have characterised the reduction of nitrate by a monomolecular molybdenum (III) species in aqueous solutions. Nitrate reduction is catalysed by nitrate reductases which are molybdoproteins<sup>1</sup>. Nitrate is reduced to nitrite by nitrate reductase, the nitrite being further reduced to ammonium ions by nitrite reductase which contains iron but no molybdenum<sup>2</sup>. Evidence indicates that nitrate reductases are monomolecular in molybdenum<sup>3,4</sup>. Therefore, a molybdenum-based model system for nitrate reductase should be monomolecular in molybdenum and undergo a change of oxidation state of two [ $\text{Mo(III)} \rightarrow \text{Mo(V)}$  or  $\text{Mo(IV)} \rightarrow \text{Mo(VI)}$ ].

Advances in the understanding of the chemistry of  $\text{Mo(III)}$ , (refs 5–8), the observation that  $\text{Mo(III)}$  reduces nitrate non-enzymatically<sup>9</sup> and the suggestions<sup>10,11</sup> that the  $\text{Mo(III)/Mo(V)}$  couple may be involved in certain enzymes containing molybdenum have led us to study the reaction between the hexaquo-molybdenum cation,  $\text{Mo(H}_2\text{O)}_6^{3+}$ , and nitrate.

The reaction between  $\text{Mo(H}_2\text{O)}_6^{3+}$  and nitrate was followed spectrophotometrically in 1 M *p*-toluene sulphonic acid (HPTS) in strict anaerobic conditions (argon). Representative spectra for both  $\text{Mo(H}_2\text{O)}_6^{3+}$  and nitrate are presented in Fig. 1. The absorption spectrum of nitrite in 1 M HPTS exhibits a multi-component band (vibrational fine structure) between 350 and 400 nm which is attributable to the  ${}^1\text{B}_1 \rightarrow {}^1\text{A}_1$  electronic transition ( $n \rightarrow \pi^*$ ). The  $\text{Mo(H}_2\text{O)}_6^{3+}$  in the same solvent had a low absorption at 293 nm, indicative of the purity of the preparation<sup>8</sup>. When solutions of  $\text{Mo(H}_2\text{O)}_6^{3+}$  ( $4.2\text{--}4.7 \times 10^{-4}\text{ M}$ ) were mixed with excess nitrate ( $1.33 \times 10^{-2}\text{ M}$ ) in pseudo first-order conditions and the reaction allowed to proceed to completion, nitrite absorption between 350 and 400 nm was concomitant with an increase in absorbance at 293 nm. The molybdenum species resulting from the oxidation by nitrate, or by air oxidation in independent experiments, had a spectrum between 340 and 280 nm identical to that of  $\text{Mo}_2\text{O}_4(\text{H}_2\text{O)}_6^{2+}$ , as reported by Ardon and Pernick<sup>12</sup>.

The kinetics of the reaction between  $\text{Mo(H}_2\text{O)}_6^{3+}$  and nitrate were determined using five different preparations of  $\text{Mo(III)}$  (containing varying amounts of  $\text{Mo}_2\text{O}_4(\text{H}_2\text{O)}_6^{2+}$ ) at  $28.5 \pm 0.5^\circ\text{C}$  in 1 M HPTS in the presence of  $1.33 \times 10^{-2}\text{ M}$  nitrate. The  $k_f[\text{Mo}_2\text{O}_4^{2+}]$  was found to be  $2.92 (\pm 0.27) \times 10^{-2}\text{ l mol}^{-1}\text{ s}^{-1}$ . Detectable nitrite was not produced from nitrate in identical conditions when  $\text{Mo}_2\text{O}_4(\text{H}_2\text{O)}_6^{2+}$ —prepared either by the oxidation in air of  $\text{Mo(H}_2\text{O)}_6^{3+}$  or by the reduction of  $\text{Na}_2\text{MoO}_4$  by hydrazine—was substituted for  $\text{Mo(III)}$ . Moreover, the spectrum of  $\text{Mo}_2\text{O}_4(\text{H}_2\text{O)}_6^{2+}$  in 1 M HPTS did not change during 1 h of observation either in the presence or absence of  $1.33 \times 10^{-2}\text{ M}$  nitrate. The reduction of nitrate to nitrite by  $\text{Mo(V)}$  in the presence of  $\text{Cl}^-$  in tartrate buffer<sup>13</sup> is approximately 10 times slower than the reduction of nitrate by  $\text{Mo(III)}$  reported here.

The concentration of the products of the reaction between  $\text{Mo(H}_2\text{O)}_6^{3+}$  and  $\text{NO}_3^-$  indicate the presence of one dimolybdenum species and 2 mol of nitrite (Table 1). The concentration of  $\text{Mo}_2\text{O}_4(\text{H}_2\text{O)}_6^{2+}$  was measured spectrophotometrically, just before oxidation in air, and the concentration of the nitrite was subsequently determined colorimetrically<sup>14</sup>. Nitrite eventually disappeared from the solutions, suggesting that  $\text{Mo(V)}$  reduces nitrite as previously observed<sup>15</sup> in different conditions. When the reaction was allowed to go to completion, all of the  $\text{Mo(H}_2\text{O)}_6^{3+}$  present (the total molybdenum)

**Table 1** Stoichiometry of the oxidation of  $\text{Mo}(\text{H}_2\text{O})_6^{3+}$  by nitrate

Experiment	Total Mo ( $\times 10^4\text{M}$ )	$[\text{NO}_2^-] (\times 10^4\text{M})$	$[\text{Mo}_2\text{O}_4^{2+}] (\times 10^4\text{M})$	Ratio $[\text{NO}_2^-]/[\text{Mo}_2\text{O}_4^{2+}]$
1	4.70	4.90	2.24	2.19
2	4.18	2.37	1.16	2.04
3	4.45	3.24	2.18	1.49
4	4.50	1.28	0.72	1.78
5	4.50	2.44	1.32	1.70

Nitrite measured colorimetrically,  $\text{Mo}_2\text{O}_4(\text{H}_2\text{O})_6^{2+}$  measured spectrophotometrically. Average ratio and standard deviation of  $[\text{NO}_2^-]/[\text{Mo}_2\text{O}_4^{2+}]$  was  $1.84 \pm 0.28$ .

was accounted for in the  $\text{Mo}_2\text{O}_4(\text{H}_2\text{O})_6^{2+}$  formed. So the overall reaction can be represented by:

The stoichiometry was confirmed by the values obtained for the ratio  $k_f[\text{NO}_3^-]/k_f[\text{Mo}_2\text{O}_4^{2+}]$  (not shown). The nitrite concentration was measured during the reaction by adding sulphanic acid and N-1-naphthyl-ethylenediamine to the reaction mixture and recording the change in absorbance at 560 nm with time. The value of  $k_f[\text{NO}_3^-]$  (five independent determinations) was  $2.08 \pm 0.10$  times that of  $k_f[\text{Mo}_2\text{O}_4^{2+}]$ . The values for the  $k_f[\text{Mo}_2\text{O}_4^{2+}]$  were higher in the presence of the nitrite-trapping reagents, which may be attributable to their ability to pull the reaction to completion, and/or the effective removal of nitrite may prevent the further oxidation of  $\text{Mo}_2\text{O}_4(\text{H}_2\text{O})_6^{2+}$  produced in the reaction.

The reaction of nitrate with  $\text{Mo}(\text{H}_2\text{O})_6^{3+}$  is approximately 10 times faster than the reaction reported by Guymon and Spence<sup>13</sup> for the reduction of nitrate by Mo(V). Moreover, the reaction of  $\text{K}_3\text{MoCl}_6$  with nitrate at pH 7.0 was too fast to measure by classical techniques, indicating that the reaction between Mo(III) and nitrate is faster at biological pH values than in the acid solutions investigated. We were unable to obtain kinetic data on the reaction between  $\text{Mo}(\text{H}_2\text{O})_6^{3+}$  and nitrate at biological pH values because of the formation of molybdenum precipitates.

Nitrate reductases seem to contain one atom of molybdenum at each active centre. Preliminary EPR data demonstrate that

**Fig. 1** Spectra of a,  $\text{NO}_2^-$ ; b,  $\text{Mo}(\text{H}_2\text{O})_6^{3+}$ ; c,  $\text{Mo}_2\text{O}_4(\text{H}_2\text{O})_6^{2+}$  and  $\text{NO}_2^-$  produced by the oxidation of  $\text{Mo}(\text{H}_2\text{O})_6^{3+}$  by  $\text{NO}_3^-$ . All spectra in 1 M HPTS.

molybdenum can exist in the (V) oxidation state; one report<sup>18</sup> indicates that the Mo(V) state is the oxidised form of the enzyme, since the EPR signal disappears on reduction of the enzyme. Physiological substrates for nitrate reductases include  $\text{H}_2$ , NADPH,  $\text{H}^+$  and NADH,  $\text{H}^+$  (ref. 1). Therefore, a monomolecular molybdenum species in nitrate reductase undergoes a two-electron redox reaction and it is possible that Mo(V) is the oxidised molybdenum species.

A number of inorganic models for nitrate reductase involving the Mo(V)/Mo(VI) couple have been reported<sup>13,17-20</sup>. They all involve a single electron transfer and have the disadvantage that nitric oxide or a nitrogen (IV) oxide is formed as the reduced product. They represent models for enzymic nitrate reduction only if one postulates that molybdenum exists in a hydrophobic region of the enzyme. The nitrogen (IV) oxide formed in this hydrophobic region would undergo a disproportionation in the aqueous enzyme solvent resulting in the formation of nitrite and nitrate<sup>18</sup>.

On the other hand, the Mo(III)/Mo(V) model shown here involves an overall two electron transfer, could take place in either an aqueous or a hydrophobic (depending on the ligands involved in the molybdenum coordination) region of the enzyme, and produces nitrite as the reduced product and Mo(V) as the oxidised product. Moreover, the Mo(III)/Mo(V) couple is monomolecular in molybdenum; the dioxymolybdenum (V) species being formed in aqueous environments by the dimerisation of a presumed  $\text{MoO}_2^+(\text{V})$  species. These arguments suggest that the reduction of nitrate by  $\text{Mo}(\text{H}_2\text{O})_6^{3+}$  is a valid model system for nitrate reductase.

Williams<sup>20</sup> has postulated an oxygen atom transfer mechanism to explain the biological reduction of nitrate which is reformulated in Fig. 2.

**Fig. 2** Postulated oxygen atom transfer mechanism for the enzymic reduction of nitrate by  $\text{Mo}(\text{H}_2\text{O})_6^{3+}$ , assuming NADPH,  $\text{H}^+$  to be the substrate for the reduction of  $\text{MoO}_2^+(\text{H}_2\text{O})_4$  to  $\text{Mo}(\text{H}_2\text{O})_6^{3+}$ . The net overall reaction is  $\text{NADPH}, \text{H}^+ + \text{NO}_3^- \rightarrow \text{NADP}^+ + \text{NO}_2^- + \text{H}_2\text{O}$ .

This mechanism is consistent with (although not proven by) our data. This scheme postulates that the potential of the enzymic Mo(III) is sufficiently negative to reduce nitrate. The  $\text{MoO}_2^+(\text{V})$  produced is reduced by the enzymic electron transport chain which donates 2 electrons and 2 protons. The reactions presented are compatible with the electron transport studies<sup>16,21,22</sup> on nitrate reductases, which position molybdenum at the terminal end of the electron transport chain and are consistent with the known physiological substrates which donate 2 electrons and 2 protons to the electron transport chain.

We thank the NSF for support and Mrs Martha Somerville Owens for technical assistance.

## Relevance of oxygen ligands to reduction of ligating dinitrogen

We have reported<sup>1</sup> the reduction of dinitrogen, in *cis*-[M(N<sub>2</sub>)<sub>2</sub>-(PMe<sub>2</sub>Ph)<sub>4</sub>] (*A*, where M = Mo or W), to ammonia, on treatment with sulphuric acid in methanol at 20 °C. The reaction of the molybdenum complex is complete in 3–4 min but the yield (≤ 0.8 mol per Mo atom) is only about half that from the tungsten complex (≤ 1.8 mol per W atom), which requires about 0.5 h for complete reaction. We now find that ammonia is produced almost equally well, (1.7 mol per W atom), but much more slowly, from a methanol solution of *A*, (with M = W) either at the boil (3–4 h) or on irradiation for 30 h at 20 °C (2 × 150-W tungsten filament lamps); a boiling ethanol solution yields only 0.4 mol NH<sub>3</sub> per W atom. In contrast, *A*, (with M = Mo) gives very little ammonia (only 0.08 mol per Mo at best) in any of the above conditions; instead it evolves dinitrogen and dihydrogen.

It is not clear why the molybdenum complex produces so little ammonia from its reaction with methanol alone, in contrast to both its reaction in presence of sulphuric acid and the reactions of its tungsten analogue. One dinitrogen molecule is rapidly lost in all reactions of *A*, (M = W or Mo) leading to some intermediate which, in accord with the general chemistry of molybdenum and tungsten, should probably be more labile in the molybdenum series.

This greater lability may account for a more ready loss of the second dinitrogen ligand from molybdenum and the generally lower yields of ammonia. The greater lability may also be particularly damaging when the intermediate is a methanol- or methoxy-hydrido complex in boiling methanol rather than a sulphato- or other oxo-anion complex at 20 °C. It is, however, possible that the tungsten and molybdenum complexes yield ammonia by different chemical mechanisms<sup>2</sup>.

In both the tungsten and the molybdenum series of complexes, the protonation of N<sub>2</sub> to NH<sub>3</sub> in good yield seems to depend on the replacement of the tertiary phosphine ligands by ligands ligating through oxygen (for example, OH<sup>-</sup>, SO<sub>4</sub><sup>2-</sup>, MeOH). All are replaced from the tungsten complexes, but perhaps only two from the molybdenum. Sulphate is the most effective oxo-anion tried, but others, including phosphate, are almost as good. Chloride and bromide are less effective (our unpublished results).

The importance of ligating oxygen probably lies in its effectiveness as a  $\pi$ -electron donor to early transition metals especially in higher oxidation states. The progressive replacement of the first dinitrogen molecule, which is a strong  $\pi$ -acceptor, and the tertiary phosphine ligands (weak or neutral  $\pi$ -acceptors) by the  $\pi$ -donor oxygen ligands progressively raises the d-electron energy levels on the metal atom, so that electrons pass from the metal to the second dinitrogen molecule as its protonation proceeds; possibly by a mechanism outlined in ref. 2. Chloride and bromide are less effective as  $\pi$  donors and

so lend themselves to the isolation of complexes containing dinitrogen in intermediate stages of reduction<sup>2</sup>.

Oxygen ligands are undoubtedly important in promoting the protonation and reduction of ligating dinitrogen to hydrazine or ammonia in suitable early transition metal (groups IV to VI) complexes. Whenever reasonable yields (for example, > 0.1 mol N<sub>2</sub>H<sub>4</sub> or > 0.2 mol NH<sub>3</sub> per transition metal atom) of nitrogen hydrides have been obtained by protonation of a dinitrogen complex, an oxygen ligand, or an oxygen-containing solvent, such as hydroxide<sup>3</sup>, catechol<sup>3</sup>, ether<sup>4</sup>, methanol-sulphuric acid<sup>1</sup>, propylene carbonate or *N*-methylpyrrolidone<sup>5</sup>, has been involved.

This observation raises the question as to whether, in nitrogenase, the molybdenum, assumed to be the active site, is in an oxygen environment. Chemical evidence seems to point in that direction because almost quantitative yields of hydrazine have been obtained from dinitrogen by its reaction with V(OH)<sub>2</sub> either in aqueous alkaline suspension or in solution with catechol<sup>3</sup>. This demonstrates that molecular nitrogen can interact with early transition metal ions in oxidation states accessible in aqueous solution, and presumably also in other oxygen or oxygen-nitrogen environments such as may ligate molybdenum in the enzyme.

## Elevation of selenium levels in air by xerography

ROOMS in which xerography machines are used for document reproduction frequently have a strong, characteristic 'selenium' smell. It seemed likely that this is caused by selenium compounds released from the selenium plates or drums charged with high voltages in the photosensitising step of the photoelectric printing process. To test this hypothesis, we sampled the air in an unventilated room (48 m<sup>3</sup> in volume) housing a xerographic machine, on which some 450–475 copies were reproduced in intermittent use daily. The air was drawn by a small sampling pump at a rate of 1 foot<sup>3</sup> h<sup>-1</sup> through a fritted diffuser into 20 ml of 0.1 N NaOH for 9 h d<sup>-1</sup> for 4 d. The selenium trapped (0.005–0.015  $\mu$ g) was determined according to the fluorimetric method of Olson<sup>1</sup>.

Values obtained in replicate runs lay between 20 and 60 ng of selenium (as Se) per m<sup>3</sup> of air. The variation in levels may be ascribed to differences in the number of copies made and the non-compliance of users of the machine with a request to keep the door of the room closed during the sampling periods.

The levels found were thus invariably much higher than the 1.2 ng m<sup>-3</sup> measured in the San Francisco Bay area<sup>2</sup>, a level already considered to be elevated 2,400 times beyond the natural background accountable for in terms of soil and seawater contents. Average levels of 0.9 ng m<sup>-3</sup> Se were found in seven air samples taken in the Cambridge, Massachusetts area<sup>3</sup>.

Selenium is an essential trace element for bacteria and animals, and probably also for plants<sup>4</sup>; however, there seems to be a rather narrow range of beneficial selenium availability. Below certain levels, signs of selenium deficiency occur and at somewhat higher levels, signs of

selenium toxicity can become apparent<sup>5-7</sup>. Tolerable levels are influenced by environmental factors.

Whether elevated selenium levels in xerography rooms are hazardous remains to be seen, but avoidance of selenium buildup by good ventilation may well be indicated.

## Do birds use waves for orientation when migrating across the sea?

MIGRATING birds apparently can determine their intended flight direction with reference to the Sun, the stars or the magnetic field<sup>1-3</sup>. This mechanism, however, cannot be used to prevent wind drift. We suggest that for this purpose they orientate themselves with reference to the waves when flying over the sea.

Low-flying, diurnal migrants have been found to compensate completely for wind drift over land<sup>4,5</sup>. Most radar studies have generally produced evidence of at least partial compensation in both nocturnal and diurnal migrants over sea as well as over land<sup>6-13</sup>, although some investigations indicate uncompensated wind drift<sup>14-17</sup>. Partial compensation has been interpreted in terms of 'pseudodrift'; that is complete compensation is thought to take place, but populations with different intended track directions migrate in different proportions in different wind conditions<sup>8,10</sup>.

The following means to achieve complete compensation have been proposed<sup>18</sup>: (1) continuous reference of the flight track to the landscape<sup>4,7</sup>, (2) reference to the wind in combination with initial or occasional reference to landscape<sup>9,10</sup>, (3) inertial recording of rectilinear and angular accelerations<sup>7,20</sup>.

Radar studies in southern Scandinavia of the diurnal migration of cranes *Grus grus*<sup>21</sup>, wood pigeons *Columba palumbus*<sup>22</sup> and redwings *Turdus iliacus*<sup>23</sup> have revealed incomplete compensation for wind drift over the sea, but complete compensation over land (no data were available for redwing migration over land). The variation of track directions over the sea was significantly less than would be expected if the birds drifted from fixed heading directions. Pseudodrift was observed for pigeons over land in southernmost Sweden as birds departing from different geographical areas flew in slightly different directions, and the proportion of pigeons arriving from the different areas varied with wind conditions. The drift effect was, however,

Fig. 1 Vector diagrams of bird movements in relation to wind and sea motion. The birds' ground speed and track direction ( $T$ ) are available from radar records, geostrophic wind speed and direction ( $W$ ) from ground synoptic maps. From these data, the birds' heading direction and true air speed ( $H$ ) can be calculated. If the birds drift because of the wave motion, the direction of velocity relative to the sea ( $t$ ) should be kept constant irrespective of wind to coincide with the intended track direction, and variation in direction of  $T$  should be due to variation in  $\theta$ .  $c$ , Velocity of waves;  $\gamma$ , angular difference between directions of wave movements and geostrophic winds. Dependent on whether winds blow from the left (left diagram) or right (right diagram) of the birds' track direction,  $\gamma$  should be subtracted from or added to  $\beta$  to determine the direction of  $c$ .  $\theta$  could be calculated from the equation.

$$\sin \theta = c \sin(\beta \pm \gamma) [c^2 + T^2 - 2cT \cos(\beta \pm \gamma)]^{-1/2}$$

significantly less over land than over the sea although the same birds were studied in both cases. Thus, pseudodrift cannot explain the increased amount of drift over the sea. Furthermore, these observations are at variance with the second and third (as far as pure inertial navigation is concerned) hypotheses.

In this report we present support for our hypothesis that the drift over sea was due to the birds using the wave pattern as 'landmarks'. It is reasonable to expect that the birds were not aware of the movement of the waves, but experienced the sea as a stationary landscape. We propose that the birds behaved in an analogous way over sea as over land, that is they projected their intended flight direction visually on to the wave pattern and headed into the wind to be able to fly along this course. The birds may determine the angle between their track direction and the waves by referring to irregularities, such as smaller or larger waves, of the wave landscape. (An inertial-Doppler navigating system would also be compatible with our hypothesis<sup>20</sup>.) Thus, according to our hypothesis, the birds compensated completely for wind drift in relation to the system of waves, and the resulting drift, as observed on the radar screen, was due to the motion of the sea relative to land. Orientation with reference to ocean waves has been suggested before<sup>18,24</sup>, but the consequence of drift relative to land has not been considered. This hypothesis may give a complete or partial (in combination with pseudodrift) explanation for drift over the sea, as witnessed in several studies<sup>8,16,11,13,16</sup>.

To test this hypothesis we used our data on crane, wood pigeon and redwing migration to calculate the angle between the

Table 1 Predicted amount of drift for birds migrating over the sea and orienting with reference to the wave pattern as compared with drift observed

	Fbo-L	Predicted Fbo-S	Fln-L	Fln-S	Observed $\pm 95\%$ confidence interval
Crane, Baltic Sea	0.40	0.51	0.29	0.41	0.25 $\pm$ 0.15
Wood pigeon, Baltic Sea	0.34	0.48	0.26	0.40	0.36 $\pm$ 0.17
Wood pigeon, Kattegatt	0.27	0.32	0.29	0.33	0.26 $\pm$ 0.21
Redwing, Baltic Sea	0.08	0.16	0.09	0.17	0.17 $\pm$ 0.16

Amount of drift is expressed as linear regression coefficients of  $\theta$  on  $\alpha$  (predictions) or of birds' track directions ( $T$ ) on  $\alpha$  (observations, see Fig. 1). Four predictions have been calculated on the basis of wave measurements at two different sites (Fbo and Fln) and of two different relationships between surface and geostrophic winds (see text).

**Table 2** Coefficients of linear regression of birds' track direction on the relative motion of the sea

Predicted		Observed $\pm 95\%$ confidence interval (correlation coefficient)			
		Fbo-L	Fbo-S	Fln-L	Fln-S
Crane, Baltic Sea	1	$0.54 \pm 0.28$ (0.65)	$0.48 \pm 0.26$ (0.64)	$0.74 \pm 0.39$ (0.65)	$0.59 \pm 0.33$ (0.64)
Wood pigeon, Baltic Sea	1	$0.98 \pm 0.48$ (0.67)	$0.75 \pm 0.35$ (0.69)	$1.33 \pm 0.64$ (0.68)	$0.93 \pm 0.43$ (0.69)
Wood pigeon, Kattegatt	1	$0.83 \pm 0.43$ (0.76)	$0.67 \pm 0.34$ (0.76)	$1.14 \pm 0.59$ (0.76)	$0.89 \pm 0.46$ (0.76)
Redwing, Baltic Sea	1	$1.87 \pm 1.45$ (0.70)	$0.93 \pm 0.71$ (0.70)	$1.99 \pm 1.50$ (0.71)	$1.04 \pm 0.77$ (0.71)

Linear regression coefficients of  $T$  on  $\theta$  (Fig. 1) are calculated (compare Fig. 2). Correlation coefficients are in parentheses. If birds fly on constant track directions relative to the sea, regression coefficients would be 1.

birds' track directions in relation to ground and sea, respectively, for each day of migration (Fig. 1) on the basis of the following assumptions.

(1) Waves move parallel to the surface wind direction. This assumption is of course violated in cases of rapid shifts of wind direction, but is a justifiable approximation since tides and currents are of no or little importance in the study areas<sup>25</sup>.

(2) Wave velocity ( $c$ ) was estimated from surface wind velocity on the basis of (a) measurements of wave periods in relation to winds at the lightships Falsterbo Rev (Fbo) in the southern Baltic Sea and Fladen (Fln) in the Kattegatt<sup>26</sup> (the wave period was calculated as a linear function of surface wind velocity in the interval  $3\text{--}14\text{ ms}^{-1}$ ) and (b) the theoretical relationship between wave period and velocity ( $c = p(g/2\pi)$ , where  $p$  is wave period,  $g$  is acceleration of gravity)<sup>27</sup>. The lightships were situated at sea areas with sufficient depths (30–50 m) for this factor not to impose any restrictions on wave propagation. The difference between wave movements with onshore and offshore winds (the lightships were situated 10–20 km offshore) was very small, and the combined sets of wave data were used. There was, however, a significant difference between wave movements at the two measuring stations, which cannot be explained. We therefore made separate calculations for the two stations.

(3) The birds travelled at altitudes of several hundred to a thousand metres. Direction and speed of the winds were evaluated from barometric pressure charts (geostrophic winds). Because of friction the surface wind force is reduced to about 70% of the geostrophic wind speed over the open sea (S) and 46% over land (L)<sup>28</sup>. Intermediate conditions would be expected in the study areas, due to the proximity of land, and we made separate calculations for both cases. On the basis of the above assumptions and calculations wave velocity was estimated from geostrophic wind velocity ( $W$ ) according to the equations:

$$\text{Fbo-L: } c = 3.32 + 0.111W; \quad \text{Fln-L: } c = 1.98 + 0.137W;$$

$$\text{Fbo-S: } c = 3.32 + 0.176W; \quad \text{Fln-S: } c = 1.98 + 0.219W.$$

These equations refer to average conditions determined from several thousands of observations of wave periods, and relationships would be expected to deviate at specific occasions, especially when the wind speed changes rapidly.

(4) Friction causes the surface wind direction to shift anticlockwise in relation to the geostrophic wind direction. The angle of deviation ( $\gamma$ , Fig. 1) is about  $14^\circ$  over open sea and  $38^\circ$  over land<sup>28</sup>.

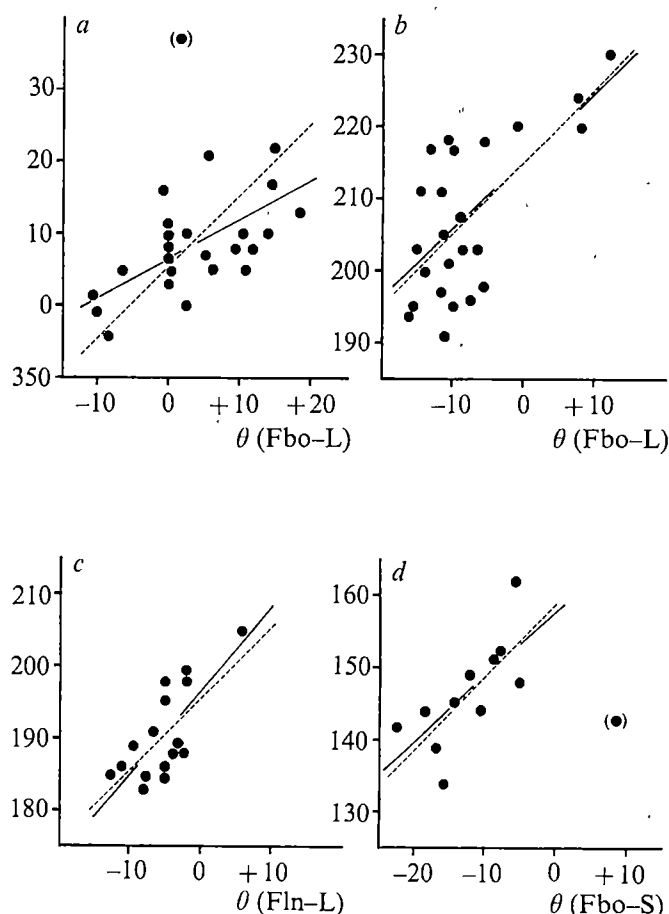

The amount of drift can be estimated on a scale from 0 (birds are flying on constant track directions) to 1 (fixed heading directions) if, by way of linear regression analysis, track directions are related to the angle between track and heading directions<sup>21–23</sup>. The amount of drift observed over sea varied between 0.17 and 0.36. These figures differ significantly from 0 as well as 1 and therefore lend no support to the hypotheses that the birds compensated completely for wind drift or that they drifted from fixed heading directions<sup>21–23</sup>. The observed amount of deflection is, however, close to what is predicted if the drift is due to the wave motion (Table 1).

If the birds are deflected due to the motion of the sea, the variation in observed track direction should be due to the variation of the angle between  $T$  and  $t$  as defined in Fig. 1. This

relationship is examined in Table 2 and Fig. 2.

Considering the uncertainties involved in applying data on the averaged relationship between waves and winds for specific instances, we think that the results form good support for the hypothesis that birds drift because of the motion of the sea.

The crossings over the southern Baltic Sea and the Kattegatt

**Fig. 2** Flight directions of birds ( $T$ ) during sea crossings in relation to the angle between track directions relative to ground and sea, respectively. The broken line (regression coefficient = 1) shows the relationship to be expected if the birds fly on fixed track directions in relation to the sea and drift by the motion of the sea. The solid line shows the linear least-squares fit to observational data (compare Fig. 1 and Table 2). One observation of crane migration is bracketed and excluded from the analysis. Mean track direction ( $037^\circ$ , only few flocks migrating) was considerably more towards the east than on any other day. Weather was different from all other occasions; strong west-south-west winds (approximately  $20\text{ ms}^{-1}$ ), low cloud ceiling, bad visibility and rain prevailed during the passage of a cyclone over southern Scandinavia. We suggest that the birds could not detect the sea, but drifted from a heading approximately pointing towards the preferred track direction ( $\alpha = 42^\circ$ ). Furthermore, data from 1 d of redwing migration are excluded, due to uncertainty about prevailing winds<sup>23</sup>. a, Crane, Baltic Sea; b, wood pigeon, Baltic Sea; c, wood pigeon, Kattegatt; d, redwing, Baltic Sea.

extend over fairly short distances (50–150 km), but cranes regularly cross much wider areas of open sea, such as the eastern Mediterranean, sometimes by night<sup>29</sup>, and the redwing, which typically migrates at night, regularly covers still longer distances over the open sea, for example, the North Sea from Norway to Britain and the Atlantic from Iceland to Britain<sup>24</sup>.

Without any points of reference for the track of flight, the birds may have to resort to heading towards the intended track direction and would consequently be drifted by the wind (or by clouds)<sup>30</sup>. By using landmarks or wave patterns they can completely (over land) or partly (over sea) compensate for the drift. Navigational ability may furnish birds with the possibility of reaching their goals in spite of drift over sea, by way of continually readjusting the intended track direction towards the goal.

It has been demonstrated that pigeons manage to home when released with frosted contact lenses (preventing detection of landmarks)<sup>31</sup> or over the sea with no sight of land<sup>32–34</sup>. In both cases, however, homing performance was worse, that is more pigeons were lost and loft re-entry times were longer, than for control birds released over land. The poor homing performance may be due to drift by winds and waves, respectively.

We thank Squadron Leader H. B. Lake, for drawing our attention to the possible effect of wave motion and explaining helicopter flying over the open sea. We also thank Dr C.-A. Bauer, Mr J. Karlsson, Dr J.-O. Mattsson, Dr G. Rudebeck and Professor S. Ulfstrand for help.

## Oscillations of tropical insect populations

SAUNDERS AND BAZIN<sup>1</sup> have suggested that “only ecosystems with relatively few species can have a sufficiently high linear connectivity to produce oscillations without becoming unstable, which would explain why it is that population oscillations are observed in the Arctic but not in the

tropics”. Most numerical studies of insect populations in the tropics have been relatively short but what longer time series there are do not bear out this statement. The more favourable temperature conditions in the tropics can allow breeding to continue throughout the year, and typically 8–10 generations may be completed each year.

Nevertheless, annual cycles of abundance are commonplace and, not infrequently, shorter term oscillations with a period equal to the generation length are evident, they must arise through the delay caused by the insect passing through its developmental stages. These ‘generation’ cycles are remarkably persistent and do not damp out with time as predicted by Lotka<sup>2</sup>. They are particularly strong in suction trap records of the coffee leaf-miners, *Leucoptera meyricki* (Guesq.) (Lepidoptera, Lyonetiidae) and *L. coffeina* (Washb.) in Tanzania<sup>3</sup>, and are observed in populations of *Planococcoides njalensis* (Laing) and *Planococcus citri* (Risso) on cocoa in Ghana. Furthermore, the idea that the greater complexity of tropical ecosystems necessarily confers on them a higher degree of stability and thus that oscillations tend to damp out seems to be largely illusory.

Of all tropical tree crops, cocoa maintains one of the most complex insect ecosystems. On a world-wide basis Entwistle<sup>4</sup> has recorded more than 2,000 associated insects, and in Ghana some 250 ant species have been recorded from cocoa. The crop is grown under thinned forest shade and is maintained in its early years with the minimum of disturbance to the underbush vegetation which persists until the cocoa canopy becomes sufficiently thick to shade it out. It is thus in intimate contact with an overstorey of forest trees and an understorey of ground vegetation, and receives its insect fauna from both sources. In particular, the ant regimes which make up the bulk of the insect biomass on cocoa seem to be superimposed on the crop from the overstorey trees. The interrelationships between the components of the cocoa ecosystem are very complicated, involving homopteran–ant mutualistic associations and territorial antagonism between the more aggressive ant species, which leads to the formation of discrete, three-dimensional ant mosaics<sup>5</sup>. Agents such as the cocoa mirids and the mealybug-transmitted, cocoa-swollen shoot virus can lead to the large scale degeneration of the cocoa canopy with a consequent impact on the other elements of the ecosystem.

Yet in spite of the complexity of the cocoa ecosystem

Fig. 1 Serial correlations of a time series comprising 186 weekly records of the percentage of trees infested by three different insect species on a block of 238 Amazon cocoa trees. a, *Steatococcus* sp.; b, *Pheidole megacephala* (F.); c, *Phenacoccus hargreavesi* (Laing).

Fig. 2 Monthly assessment on 25 farms in eastern Ghana of populations of the cocoa mirids *Distantiella theobroma* (Dist.) and *Sahlbergella singularis* (Hagl.). The counts of the two species have been combined.

many of its component populations oscillate both numerically and spatially. Figure 1 shows three correlograms obtained from a serial correlation of time series of 186 weekly records of the percentage of trees infested on a block of 238 Amazon cocoa trees. *Steatococcus* sp. (Hemiptera, Coccidae) and *Pheidole megacephala* (F.) (Hemiptera, Formicidae) show particularly strong oscillations with a period of about 1 yr, and *Phenacoccus hargreavesi* (Laing) (Hemiptera, Coccidae) shows a cycle with a period of 9.2 weeks.

Population counts of the cocoa mirids, *Sahlbergella singularis* (Hagl.) and *Distantiella theobroma* (Dist.) made at monthly intervals on 25 farms in eastern Ghana since 1965 (Fig. 2) showed an annual cycle in abundance, and perhaps a much longer term cycle.

In Tanzania, daily catches in suction traps of *Leucoptera meyricki* and *L. coffeina* on arabica coffee were made at Lyamungu, on the southern slopes of Mount Kilimanjaro between 1960 and 1968, covering in all 62 moth generations<sup>3,6</sup>, and for the last 45 generations independent estimates have been made of the density of the larvae of the two species and their associated parasites (Fig. 3). It is clear that a 16-generation (two-year) cycle is superimposed on an 8-generation (one-year) cycle. A clearer picture of

Fig. 3 Number per generation per 100 leaves of larvae of coffee leaf-miners and their larval parasites on arabica coffee in Tanzania. Generations are numbered consecutively, solid and dashed lines indicating alternate years. No counts were made in generations 7 or 23.

the perturbations of the combined host-parasite system about its mean level can be obtained by a principle components analysis of logarithmically transformed values of hosts and parasites since values along the first components axis are a linear combination of the host and parasite scores (Fig. 4). Here again the two-year cycle is very evident. Population counts of the two leaf-miner species were made at Lyamungu by Notley<sup>7,8</sup> between 1938 and 1940, and a similar two-year cycle is discernible in his data.

Fig. 4 Displacement from equilibrium of the leaf-miner-parasite system of Fig. 3 considered as a whole and expressed as distances along the first principal component axis from a principal component analysis of the logarithmically transformed numbers of leaf-miners and parasites per generation.

It seems likely that the annual leaf-miner cycle is driven by seasonal weather changes and is not caused by interactions within the system, but it is not at present obvious how an annual weather pattern could interact with the system to produce a two-year cycle. There is some evidence that the leaf-miner parasites do no more than follow the cycles of leaf-miners.

It could be argued that the lynx cycle, to which Saunders and Bazin<sup>1</sup> are presumably alluding in their reference to the Arctic, is not comparable to the leaf-miner cycle because of the great difference in periodic lengths but when the two cycles are compared in terms of generation length this apparent difference disappears. The driving force behind both cycles is obscure. Bulmer<sup>9</sup>, has suggested that the cycles of Arctic predators are caused directly or indirectly by the cycle in the snowshoe rabbit but this leaves unanswered the question of why the snowshoe rabbit population should be cyclical.

Williamson<sup>10</sup> has suggested that the standard deviation of the  $\log_{10}$  generation values can be used as a measure of population variability and thus of the amplitude of oscillations, and he quotes a number of examples. The standard deviation of the leaf-miner population is 0.768, which compares with a standard deviation of 0.558 for the lynx cycle. The leaf-miner standard deviation is similar to many of the European insects cited by Williamson<sup>10</sup> and compares with a value of 0.771 observed for the black headed budworm *Acleris variaria* (Fern) and 0.595 for the European spruce sawfly *Diprion hercyniae* (Htg) in Canada, calculated from data given by Morris<sup>11</sup>.

It is clear that not only do tropical insect populations show cyclical behaviour, but also that the amplitude of the cycles is comparable to those of temperate insects. Furthermore, even in the cocoa ecosystem, which is considerably complex and has many features in common with tropical forests, population cycling is observed in many species.

Tropical insect host-predator systems are worthy of much

closer examination if only because they have the advantage over temperate systems of a compression of the time scale by a factor of 8 to 10.

## Divergent X-ray-induced mutation rates in the mouse for *H* and "7-locus" groups of loci

INCREASED demand for nuclear power re-emphasises the need for a well-grounded estimate of the genetic risk of environmental mutagens in general and of ionising radiations in particular. With respect to germ-line, specific-locus mutation rates, estimates for man have been based primarily on the mouse 7-locus test, carried out on a large scale at Oak Ridge National Laboratory (USA) and Harwell (UK). Among the many important radiobiological findings recently summarised<sup>1</sup> are the following: the mutation rate depends on sex, on the type of germ cell irradiated, on radiation quality (X rays, neutrons), on dose rate (rad min<sup>-1</sup>), on fractionation (number of treatments during a certain period) and on total dose.

With this information in hand, we can inquire about the limitations inherent in the 7-locus test. First, is the sample of seven loci (*a*, *b*, *c<sup>h</sup>*, *p*, *d*, *se*, *s*) representative of the entire mouse genome? Second, does the test, detecting so far only the change from dominant to recessive (it can also detect wild type to dominant), adequately approximate the rates for other types of specific-locus mutational change? Two reports bear directly on these questions.

Lyon and Morris<sup>2</sup>, using 7-locus test methodology, tested five other loci together with one of the original seven (*a*, *bp<sup>H</sup>*, *fz*, *ln*, *pa*, *pe<sup>H</sup>*) in a "6-locus" test. Dominant-type males were mated to untreated females which were homozygous for recessive alleles at the loci of interest. Mutants were detected in the F<sub>1</sub> progeny by their visible recessive phenotypes, that is, by a loss of dominant allele activity. After 600 rad of X rays, the mean spermatogonial mutation rate was one-third that of the 7-locus mean.

Bailey and Kohn<sup>3</sup> screened a different and much larger (>30) set of loci (histocompatibility or *H*) whose alleles are codominant. The *H* test detected losses in antigenicity (analogous to the loss of the dominant phenotype in the 7-locus test), and also a change or gain in antigenicity, which might signal a change in one or more codons or the appearance of a new active gene. The result of their experiment with a single dose of 522 rad suggested that the *H* loci were less sensitive than the "7 loci", but did not establish the size of the difference.

We have therefore made a quantitative comparison. We used a standardised *H*-test procedure<sup>3-5</sup> in which tail-skin grafts were orthotopically exchanged in a "reciprocal circle" among syngeneic mice, 37-43 d old. Each mouse provided one graft for each of two other mice of similar sex and received two grafts in return. All grafts should have been accepted. Suspected mutants, detected on the basis of

**Table 1** Predicted number of mutants per dose group based on the results with the 7-locus test

Dose (rad)	H tested F <sub>1</sub> s	K (× 10 <sup>-7</sup> )	Predicted nos of induced mutants
Controls	2,335	—	—
Single doses			
350	1,239	2.8	3.6
500	947	2.5	3.6
650	1,285	2.2	5.5
800	1,603	1.65	6.3
Split, 1 d			
500 (150+350)	1,107	3.35	5.6
650 (300+350)	1,339	3.7	9.7
800 (300+500)	1,061	4.1	10.4
Split, 5 or 8 weeks			
650 (300+350)	1,422	2.8	7.8
800 (300+500)	1,276	2.6	8.0
Total treated	11,279	—	60.5

The predicted number of induced mutants was equal to: *H* loci tested per irradiated gamete (30) × dose (rad) × animals tested × *K*. *K* (expected rate of induction of mutations per locus per rad) was calculated separately for each of our dose groups on the basis of the Oak Ridge and Harwell statistics for the 7-locus test, given in Tables VI and VII of ref. 1. The doses there are in r.; we used them as equivalent to rad. For single exposures, the value of *K* was read from a four-point curve over the range 300-900 r. For split doses 1 d apart, *K* was read from a line determined by two points, that for a single dose of 300 r. and that for 1,000 r. given in two 500 r. fractions. This made the conservative assumption that splitting 300 r. did not increase *K*, but that such split doses become relatively more effective as the total split-dose rose to 1,000 r. For split doses 5 or 8 weeks apart (mean 52 d), no effect of fractionation was assumed; *K* for each fraction was that read from the single-dose curve. The values for the two fractions were combined to give the single equivalent value of the table.

their pattern of graft rejection 57-63 d after grafting, were backcrossed to establish transmission of mutations.

The grafted animals were the F<sub>1</sub> progeny of pretested C males (BALB/cKh) whose pelvic region had been X rayed at 105-152 d old, and who were mated 75 d later to pretested B6 females (C57BL/6Kh). The radiation factors were 250 kVcp X rays, half value layer 1.2 mm Cu; intensity, 60-65 rad min<sup>-1</sup>. We used 34 control and 214 irradiated males, who were mated with 692 B6 females. The males were kept in service for 1-1.5 yr after initiation of mating, and were mated with one female at a time.

Two classes of loci were at risk<sup>6,7</sup>. Class I loci were heterozygous in the F<sub>1</sub> animal because the B6 and C parents carried different alleles. A minimum of 30 such loci was irradiated in the C male and tested for spermatogonial mutations in the BC6F<sub>1</sub> progeny. Class II loci were homozygous and will be dealt with in a later report. Results with class II loci are consistent with those for class I.

In all, 11,279 F<sub>1</sub>s were tested for the effects of single and split spermatogonial doses of 350-800 rad. There were 2,335 controls. Results with the 7-locus test predicted that the number of induced mutants would be 60 (Table 1). We observed only one class I, C-allele mutant in the treated groups. It was of the "gain and loss" type (a specificity was lost and was replaced by a new one); its father had received 650 rad (300+350, 1 d apart). Four other class I mutations were detected (three gain and loss, and one loss), but had occurred in B6 alleles, that is, in the unirradiated maternal gamete. No class I mutants were detected in the controls. Failure to find mutants was not considered to be a failure to detect them, as more than 60 class I and II mutants in 30,000 mice have been reported<sup>3,6</sup>.

The results for the mouse with the 7-locus, 6-locus and *H* tests show that different specific-locus tests applied to the same germ cell (spermatogonium) yielded different X-ray-induced mutation rates (relative values of 60, 20 and 1, respectively). This raises the question, to what extent can any particular set of loci represent the mammalian genome in this field? The results with the *H* loci, of course, might

indicate unique factors in histocompatibility radiation genetics that do not apply elsewhere. In any event, it appears that further research with various loci is needed.

We thank the National Institute of General Medical Sciences and the National Cancer Institute for support, and B. Thompson, G. Spencer and E. White for technical assistance.

## Specific marker chromosome 14 in malignant lymphomas

A CONSISTENT structural abnormality of chromosome 14—an extra band at the terminal of the long arm—has been found in 10 out of 12 African Burkitt lymphomas<sup>1</sup>. We report here a similar long acrocentric marker chromosome derived from chromosome 14 in other types of malignant lymphoma.

The samples used were seven lymphosarcomas, three reticulum cell sarcomas, six Hodgkin's lymphomas and one follicular lymphoma. The lymphoma cells from lymph nodes, peripheral blood, bone marrow, ascites, pleural effusion and a cell line *in vitro* were cultured for 24 h in RPMI 1640 medium with 10% foetal calf serum, and the chromosome specimens were prepared as usual and banded with Giemsa<sup>2</sup>. As controls, lymph node cells from three cases with chronic lymphadenitis were examined.

Table 1 summarises the results obtained. Many cells from various lymphoma cases reveal a long acrocentric marker chromosome. This marker was found in three out

Fig. 1 Partial karyotype of D-group chromosomes of five mitotic malignant lymphoma cells banded with Giemsa. Note a longer chromosome 14 than usual in each case.

of four cases of lymphoblastic lymphosarcoma and absent in three lymphocytic lymphosarcomas. About 50% of the hypotetraploid cells of reticulum cell sarcoma in cases 8 and 9 had a similar marker although in case 10, examined after irradiation, this marker was not frequent. A similar acrocentric marker was found in three out of six cases of Hodgkin's disease. Cells with this marker were hyperdiploid in case 14, and near triploid in case 15. Both hypodiploid and near triploid cells in case 16 had this abnormal chromosome. Cases 11, 12 and 13 which were in a less advanced histological stage lacked this acrocentric marker. Abnormal

Table 1 Incidence of long acrocentric marker chromosome in malignant lymphoma cells

Case no.	Diagnosis	Total cells counted	Incidence (%)	$\frac{\text{Cells with the marker}}{\text{Total cells counted}} \times 100$
1	LSaL (lymphoblastic)	58	0	
2	LSaL (lymphoblastic)	46	19	(65% of hyperdiploid cells)
3	LSaL (lymphoblastic)	31	30	(all hyperdiploid cells)
4	LSaL (lymphoblastic)	50	100	(all near diploid cells)
5	LSaL (lymphocytic)	27	0

LSa (L), lymphosarcoma (leukaemic); HD, Hodgkin's disease; RCSa, reticulum cell sarcoma; FL, follicular lymphoma; LP, lymphocytic predominance; MC, mixed cellularity; LD, lymphocytic depletion.

\*Derived from pleural effusion of Hodgkin sarcoma. Chromosome analysis was done at the 50th transfer generation (350 d).

chromosomes were not found in the follicular lymphoma and the three chronic lymphadenitis.

Detailed analysis revealed that the marker was an abnormal chromosome 14 with a longer arm than usual, representing a tandem 14:14 long arm translocation (Fig. 1). Although some other chromosomal abnormalities were also found in the malignant lymphomas examined, none was common as the acrocentric marker involving chromosome 14.

The specific involvement of chromosome 14 in clonally proliferating human lymphocytes has been also demonstrated in ataxia-telangiectasia<sup>3,4</sup>. The above findings therefore support the hypothesis by McCaw *et al.*<sup>4</sup> that structural rearrangement of the long arm of chromosome 14 may be a step towards the development of lymphoid malignancies.

We thank Professors Taketoshi Sugiyama and Gyoichi Wakisaka for their encouragement and advice.

## Examination of ATCC stocks for HeLa marker chromosomes in human cell lines

INTRASPECIES contamination of cell cultures is a serious technical problem when more than one cell line is maintained in continuous serial subculture within a laboratory. Biochemical<sup>1-3</sup> and immunological<sup>4,5</sup> evidence has strongly suggested that many "cell lines" that are commonly used in the laboratory around the world have been contaminated with HeLa cells. Chromosome rearrangements resulting in specific "markers" provide a unique opportunity to monitor for intralinear specificity in HeLa and other human cells. Because certain cell lines in the American Type Culture Collection (ATCC) repository have already been shown to possess the type A (fast) G6PD characteristic of HeLa, we initiated a survey of these cell lines for the chromosome features described for HeLa cells<sup>6-9</sup> using the trypsin-Giemsa banding technique<sup>10</sup>. Ten cell lines, including two HeLa lines, have been studied so far. Five of these lines have been found to contain marker chromosomes typical of HeLa cells. The non-HeLa cell lines have chromosome characteristics of their own which can also be used to monitor their purity.

The HeLa S3, ATCC-CCL 2.2 and HeLa, ATCC-CCL 2, have four distinct marker chromosomes (Figs 1a and 2). Marker 1 (M1) is formed by the fusion of centromere and the long arm of chromosome 1 and the long arm of chromosome 3. Marker 2 (M2) consists of the short arm of chromosome 3 and the long arm of chromosome 5. Marker 3 (M3) is an isochromosome of the short arm of chromosome 5, and usually occurs in more than one copy. Marker 4 (M4) consists of the long arm of chromosome 11 and an arm of chromosome 19. Our views on the origin of M4 differ from those of other investigators<sup>6-8,11,12</sup>.

Marker chromosomes typical of HeLa cells (HM) are

found in the following cell lines: Detroit-6, ATCC-CCL 3; Chang liver, ATCC-CCL 13; KB, ATCC-CCL 17; AV<sub>3</sub>, ATCC-CCL 21 and FL, ATCC-CCL 62. These lines are all epithelial in general morphology and possess the fast migrating variant (type A) of the isoenzyme glucose-6-phosphate dehydrogenase (G6PD). Detroit-6 cells lack HM1 but exhibit two copies of HM2, three or four copies of HM3, and HM4 is found occasionally. Even though this cell line was reported to have originated from a male Caucasian<sup>13</sup>, quinacrine fluorescence studies did not reveal the presence of the Y chromosome. In addition, there is a large isochromosome (LI) formed by the duplication of the long arm of chromosome 10 (Fig. 2). The Chang liver line exhibits all four HeLa-like markers, two copies of HM1, one copy of HM2, four copies of HM3 and a single copy of HM4 (Fig. 2). In the KB line, reported to have originated from a male Caucasian<sup>14</sup>, HM1 is missing but one copy of HM2, four copies of HM3 and a single copy of HM4 are present. There is a large submetacentric (LSC) marker chromosome probably formed by the translocation between an arm of chromosome no. 3 and the long arm of chromosome 7 (Figs 1c and 2). Quinacrine fluorescence studies also revealed the absence of the Y chromosome in this line. The AV<sub>3</sub> cell line does not reveal the presence of HM1 or HM2, however, three copies of HM3 and one copy of HM4 are noted. A large submetacentric chromosome (LSC), similar to the one found in KB is present (Fig. 2). All four marker chromosomes typical of HeLa cells are found in the FL line. Three copies of HM3 and two copies of HM4 are always present. In addition, these cells possess one large submetacentric chromosome, two large isochromes and one medium-sized isochromosome. The large submetacentric chromosome (LSC) is formed by chromosome 2 with a terminal duplication of the long arm. The large isochromosome (LI 1) is formed by the duplication of the long arm of chromosome 7 and the second large isochromosome (LI 2) is formed by the duplication of the long arm of chromosome 9. The medium-sized isochromosome is formed by the duplication of the long arm of chromosome 14 (Figs 1b and 2).

Marker chromosomes typical of HeLa cells are not found in the following cell lines: RPMI 2650, ATCC-CCL 30 (Fig. 1d); RD, ATCC-CCL 136 and Detroit 562, ATCC-CCL 138. These lines also have an epithelial morphology but possess the slow migrating variant (type B) of G6PD. The RPMI 2650 cells possess the Y chromosome as determined by the quinacrine fluorescence technique. Examination of RD and Detroit 562 lines using the same technique did not reveal the Y chromosome which would be expected since they are of female origin. Detroit 562 cells contain a large submetacentric marker chromosome probably formed by chromosome 5 with a terminal duplication of the long arm.

Table 1 summarises our findings. The absence of the Y chromosome, possession of G6PD type A and the presence of HeLa marker chromosomes provide strong evidence that Detroit-6 and KB are cross contaminated with HeLa cells. Although the donor sex and racial origin of the Chang liver and FL are unknown, the fact that they both possess all four HeLa marker chromosomes indicates the possibility that these lines also are cross contaminated with HeLa cells. The AV<sub>3</sub> which is of negro origin and donor sex unknown, likewise possesses HeLa marker chromosomes. The absence of certain HeLa marker chromosomes in some of these cell lines may be due to partial contamination with HeLa cells probably through somatic cell hybridisation. The other possibility is that the gain or loss of these markers, after their initial appearance in the HeLa-contaminated parental stock, could represent no more than random effects of different culture conditions in different laboratories. The occurrence of identical large submetacentric chromosomes (LSC) in both the KB and

Fig. 1 *a*, Trypsin-Giemsa banded metaphase chromosomes of HeLa, S3, ATCC-CCL 2.2. Arrows indicate marker (M) chromosomes. *b*, Trypsin-Giemsa banded metaphase chromosomes of FL, ATCC-CCL 62. Arrows indicate HeLa-like markers (HM), large and medium-sized isochromosomes (LI 1, LI 2 and MI) and a large submetacentric chromosome (LSC). *c*, Trypsin-Giemsa banded metaphase chromosomes of KB, ATCC-CCL 17. Arrows indicate HeLa-like markers (HM) and a large submetacentric chromosome (LSC). *d*, Trypsin-Giemsa banded metaphase chromosomes of RPMI 2650, ATCC-CCL 30. Note the lack of HeLa-like marker (HM) chromosomes.

AV<sub>3</sub> indicates that these two cell lines might have been cross contaminated with each other or that these two identical markers arose independently of each other. At the time when these certified cell lines were deposited in the ATCC Animal Cell Repository as frozen ampoules, technology was not available to check for intraspecific cell contamination. With modern techniques it is now possible to monitor cell lines for cross contamination of this kind. Since we have examined these lines carefully within two passages beyond that of the frozen seed stock, using trypsin-Giemsa banded marker chromosomes, these lines were undoubtedly already contaminated with HeLa cells before reaching the ATCC Repository. On the other hand, lack of HeLa-like markers coupled with the findings for G6PD and the Y chromosome clearly indicate that RPMI 2650, RD and Detroit 562 are not cross contaminated with HeLa cells (Table 1).

Thus it seems that investigators who culture more than one cell line in the laboratory at the same time run a high risk of cross contaminating their cultures. Consequently, all cell lines should be periodically and frequently monitored through isoenzyme analysis, chromosome banding and immunological techniques to prevent intra- or interspecies contamination.

*Note added in proof:* The above information is already incorporated in a new edition of the ATCC catalogue (ATCC Catalogue of Strains II, first edition, 1975). A discussion of the intraspecific cell contamination problem appears in the introduction and all of the ATCC stocks which are known to bear HeLa-like characteristics are clearly marked in the catalogue. We are currently examining all other ATCC stock of human cell lines for chromosome features characteristic of HeLa cells and the information will be made available in subsequent publications.

Since the submission of this manuscript for publication

## Vertical transmission of tumour resistance in guinea pigs

BOTH intact bacillus Calmette-Guerin (BCG)<sup>1-3</sup> and the methanol extraction residue (MER) fraction<sup>4</sup> of BCG have had extensive application in tumour immunotherapy. Treatment with MER nonspecifically stimulates both the cellular and humoral immune systems<sup>4,5</sup>, and has been successful in tumour immunotherapy in a number of animal models<sup>6,7</sup>. Experiments in our laboratories, using animals obtained from the Weizmann Institute, Rehovot, Israel, have shown that about 40% of strain 2 guinea pigs injected with MER or with the supernatant of sonically-disrupted BCG (BCG-SS), 1-2 months before intradermal inoculation with 10<sup>6</sup> cells of the transplantable line 10 hepatocarcinoma<sup>8,9</sup>, are resistant to the growth of this tumour<sup>10</sup>. Similarly, injection of MER into developing tumour nodules 7d after tumour cell implantation results in complete tumour regression in approximately 40% of the animals tested (M.A.W., P.M. and D.W.W., unpublished).

Previous studies have demonstrated that specific antibodies can traverse the placental barrier from maternal to foetal guinea pigs<sup>11</sup>. About 50% of the offspring of BCG-SS-treated female guinea pigs that became resistant to line 10 tumour were themselves resistant to challenges with line 10 tumour cells<sup>12</sup>.

We became interested in whether a similar transfer of protection against this tumour might also occur following treatment with MER, and what the mechanism of this vertical transmission might be. Line 10 hepatocarcinoma (B. Zbar, National Cancer Institute, Bethesda, Maryland) was maintained in ascites form by intraperitoneal passage in strain 2 guinea pigs (bred at Weizmann Institute). Tumour cells were collected and prepared for intradermal inoculation as described previously<sup>10</sup>. Nine tumour-free female guinea pigs, which had been treated with single doses of MER (0.5–1.0 mg) (Department of Drug Research and Development, National Cancer Institute) or BCG-SS (50 µg N) before or after tumour cell implantation and which were resistant to further challenge ( $10^7$  cells), were mated with normal males at least 60 d after their initial tumour cell challenge ( $10^6$  cells). The newborn guinea pigs of these matings were inoculated intradermally with  $10^6$  tumour cells when approximately 30 d old and numbers of survivors and mean days of death recorded (Table 1). Age-matched offspring of seven normal guinea pigs served as controls. Complete tumour regression was observed in 11 of the 26 experimental animals tested (42%), whereas a considerable delay in onset of death was observed in nine others (experiments 2, 5, 6 and 7). No differences were observed between the capacities of male and female newborns to survive tumour challenge. Growing tumour

nodules were observed in all guinea pigs by 4 d after tumour cell implantation. In those animals which developed complete resistance to the tumour, these nodules became progressively smaller from about 7 d after tumour challenge and eventually disappeared. In the case of many guinea pigs which eventually succumbed, tumour growth was markedly retarded at the site of implantation, and it was only following the appearance of palpable metastatic lesions in the regional lymph nodes that progressive tumour enlargement and death ensued. In contrast, rapid tumour growth at the site of initial challenge followed by death was observed with each of 19 age-matched controls ( $P < 0.001$ ;  $\chi^2$  test). In three cases (Table 1, experiments 8–10), the tumour resistant female offspring of MER-treated animals were themselves mated with normal males and the third generation guinea pigs challenged with  $10^6$  tumour cells as described above. Vertical transmission of tumour resistance was again observed; three of the eight third generation offspring survived tumour challenge as opposed to none of the six age-matched controls.

To evaluate whether a transplacental transfer of immune factors was taking place, some of the maternal tumour-resistant animals of Table 1 and their offspring were skin tested, 3 d before and 3 weeks after tumour cell challenge, with 0.1 ml each of purified protein derivative of *Mycobacterium* (PPD, Ministry of

Agriculture, Weybridge, UK), soluble tumour antigen extract (SA-10, prepared by 3 M KCl extraction as described previously<sup>13</sup>), soluble normal liver antigen extract (SA-N, prepared as above<sup>13</sup>), and isotonic saline (NaCl). Areas of induration were measured after 24 and 48 h. Tumour-resistant mothers showed significant delayed cutaneous hypersensitivity (DCH) to both PPD and SA-10 but not to either SA-N or NaCl. There was no significant response by either tumour-resistant or susceptible offspring to these antigens before challenge with tumour cells. Three weeks after challenge, however, all the offspring of tumour-resistant and control mothers had DCH reactions to SA-10. Thus, DCH to SA-10 and PPD did not seem to be transmitted transplacentally to these newborn guinea pigs, and the development of DCH to SA-10 after tumour challenge was not related to their ultimate survival.

The possibility that vertical passage of immune serum elements might occur was assessed. Each of three MER-treated and tumour-resistant guinea pigs were injected intramuscularly with  $10^7$  tumour cells to stimulate both cellular and humoral anti-tumour immunity. These animals, all of which showed strong DCH reactivity to SA-10 (10 µg), were bled 3 and 7 days after immunisation, and 1 ml aliquots each of serum, plasma or whole blood cells were passively transferred by cardiac puncture to ten normal 25-d-old recipients. The latter were challenged 7 d later with  $10^6$  tumour cells. No retardation of either tumour growth or onset of death was observed in any of these animals.

To study the possible role of the milk of nursing mothers as a source of tumour resistance, the newborn offspring of each of three MER-immunotherapy-cured females and three female controls were interchanged as indicated in Table 2. The 17 newborn guinea pigs in this 'criss-cross' experiment were challenged with  $10^6$  cells when about 30 d old. Four of the nine offspring of MER-treated, tumour-resistant mothers were themselves resistant to growth of the line 10 hepatocarcinoma, in spite of having been suckled on normal lactating females. By contrast, tumour-resistant females seemed to be unable to transfer resistance by nursing to any of the eight offspring of control mothers. This finding is in agreement with the observation that guinea pig IgG antibodies are not transmitted through the milk<sup>14</sup>. Parallel experiments (Table 2) showed that none of the 14 newborn guinea pigs born to normal mothers but fathered by MER-treated tumour-resistant males resisted challenge with line 10 cells.

In summary, vertical transmission of resistance to the transplantable guinea pig line 10 hepatocarcinoma from MER-treated tumour-resistant mothers has been demonstrated. The nature of the mechanisms responsible for this protection remains to be elucidated. It is clear, however, that they are not related to factors transmitted through the milk. The fact that a significant proportion of the third generation offspring of resistant guinea pigs are also tumour-resistant makes it unlikely that this phenomenon is attributable to any lingering effect of MER or BCG-SS. Tests for DCH did not reveal evidence of cellular anti-tumour immune activity in the offspring of tumour-immune mothers, before skin challenge with line 10 hepatocarcinoma cells. Nevertheless, the considerations that small quantities of anti-tumour antibodies and/or specifically sensitised small lymphocytes may be transported across the placental barrier cannot be ruled out and are presently under investigation.

## Gene that controls initiation of chromosome replication and prophage induction in *Bacillus subtilis*

THE mechanism of initiation of the chromosome replication cycle in bacteria is beginning to be elucidated by genetic and biochemical studies<sup>1-3</sup>. But little is known about what controls the initiation frequency which has a key role in regulating the rate of DNA synthesis in response to the change in bacterial growth rate<sup>4,5</sup>. The existence of such a regulatory entity—initiator—synthesised in harmony with the increase in cell mass or the change in the cell or replication cycle, has been hypothesised<sup>6,7</sup>. We have investigated the nature of the hypothetical regulator, based on the assumption that the induction of prophage and the initiation of host cell chromosome replication would be controlled by a common regulator directly or indirectly. The assumption is based on observations that the inducibility of prophages and the initiation frequency of chromosome replication share common features in their responses to the bacterial growth rate and to the inhibition of DNA replication<sup>4,5,8-10</sup>. We assumed that the regulatory material, substance X, accumulates in the cell depending on growth rates and is consumed to initiate each replication cycle, and

that an unbalanced accumulation of X caused by the inhibition of DNA synthesis would provoke prophage induction. If this assumption is correct it should be possible to isolate conditional mutants in which both the initiation of chromosome replication and prophage induction are prevented in non-permissive conditions.

Induction of a temperate phage SPO2 in *Bacillus subtilis* by 6-*p*-hydroxyphenylazouracil (HPUra)<sup>11</sup> was used as a test system because the uracil analogue inhibited semi-conservative DNA replication by interacting specifically with DNA polymerase III of *B. subtilis*, without affecting either the repair synthesis<sup>12</sup> of the cell or the replication of the phage DNA. Most of the commonly used inducing agents, such as ultraviolet irradiation, mitomycin C (mit C) and nalidixic acid are not suitable for this test because they cause damage in the DNA molecule, which in turn may affect prophage inducibility<sup>13,14</sup>.

*B. subtilis* 168 (trp<sup>-</sup>), CRK1000, was lysogenised with the phage SPO2 and mutated with nitrosoguanidine<sup>10</sup>. The resultant mutagenised lysogens were grown in a rich Lp medium<sup>15</sup> at 30 °C and then heated to 45 °C with the addition of HPUra 5 min after heating. After 60 min of incubation at 45 °C survivals were collected on a filter paper and washed to remove HPUra. From these cells temperature-sensitive (*ts*) mutants were isolated by a conventional replica method. Properties of 133 *ts* mutants isolated in several experiments are summarised in Table 1. Thirty-seven mutant lysogens which showed both temperature-sensitive growth and temperature-sensitive induction (no induction by HPUra at 45 °C were isolated either spontaneously or after treatment with nitrosoguanidine. A double selection by repeated HPUra induction at 47 °C

isolated this type of mutant. The mutation in the host chromosome was demonstrated directly by introducing the *ts* character into a recipient, thy<sup>-</sup> cell. The resultant transformants carried *ts* and thy<sup>-</sup> characters and therefore DNA synthesis in them was measured by <sup>3</sup>H-thymidine incorporation. Ten out of 31 transformed mutant strains

**Fig. 1** Growth and DNA synthesis of *dna-ts* initiation mutant, CRK2605 (*ts*1315) and CRK2001 (*ts*27). Cells of CRK2605 or CRK2001 were grown in Lp medium containing necessary amino acid and <sup>3</sup>H-thymidine (0.5  $\mu$ Ci per 5  $\mu$ g per ml) until an early exponential phase when the temperature of the culture was shifted quickly to 47 °C. At various times before and after the shift, 0.5 ml samples were taken to measure radioactivities incorporated into the DNA fraction after incubation in 0.2 M NaOH at 80 °C for 30 min, followed by precipitation in 10% trichloroacetic acid. In parallel with this measurement DNA was isolated from 5-ml samples and its transforming activities for adenine and methionine were determined. Marker frequency analysis was done as before<sup>18</sup>. A mutant strain CRK3000 (*leu*<sup>-</sup>, *metB*<sup>-</sup>, *purA*<sup>-</sup>, *hisA*<sup>-</sup>) was used as recipient. *a*, CRK2605; *b*, CRK2001.  $\circ$ , <sup>3</sup>H-thymidine incorporation;  $\bullet$ , cell turbidity in Klett unit;  $\blacktriangle$ , *purA/metB*.

**Fig. 2** Effects of HPUra and mitC on induction and infection of SPO2 in a mutant carrying *ts-dna-ind* mutation, CRK2605. CRK2605 or its lysogen, CRK2605(SPO2), was grown in complete Lps medium (which is Lp plus MgSO<sub>4</sub>, 5 mM, and MnCl<sub>2</sub>, 0.5 mM) at 30 °C. At an early exponential phase, cells were treated as below and the turbidity was measured using a Klett colorimeter. After the last turbidity measurement, all the culture was added to Na<sub>2</sub>S<sub>2</sub>O<sub>3</sub> (final 25 mM) and stored at 4 °C overnight to determine the phage titre by the method of Okubo and Romig<sup>19</sup>. *a*, CRK2605(SPO2) was heated to 47 °C at time zero and drugs were added 5 min later. Incubation was continued at 47 °C.  $\square$ , No drug,  $4.2 \times 10^6$  plaque-forming units per ml (PFU ml<sup>-1</sup>) in the lysate;  $\circ$ , with HPUra (70  $\mu$ M),  $2.5 \times 10^7$  PFU ml<sup>-1</sup>;  $\bullet$ , with mit C (1  $\mu$ g ml<sup>-1</sup>),  $6.3 \times 10^6$  PFU ml<sup>-1</sup>. *b*, CRK2605 was heated to 47 °C at time zero and the phage SPO2 (multiplicity of infection 0.6) was added to the culture 5 min after heating, with or without drug. Incubation was continued at 47 °C.  $\square$ , No drug added,  $2.4 \times 10^6$  in the lysate;  $\circ$ , with HPUra,  $2.1 \times 10^6$  PFU ml<sup>-1</sup>;  $\blacktriangle$ , with HPUra and rifampicin (2  $\mu$ g ml<sup>-1</sup>),  $7 \times 10^5$  PFU ml<sup>-1</sup>. *c*, CRK2605(SPO2) was added with drugs at time zero and incubation continued at 30 °C.  $\circ$ , With HPUra,  $1.9 \times 10^6$  PFU ml<sup>-1</sup> in the lysate;  $\bullet$ , with mit C,  $1.7 \times 10^6$  PFU ml<sup>-1</sup>. *d*, For comparison, the mutant lysogen carrying *ts*27, CRK2001(SPO2), was grown at 30 °C, heated to 47 °C and added with drugs as in (*a*).  $\square$ , No drug addition,  $1.0 \times 10^6$  PFU ml<sup>-1</sup> in the lysate;  $\circ$ , with HPUra,  $4.7 \times 10^6$  PFU ml<sup>-1</sup>;  $\bullet$ , with mit C,  $3.9 \times 10^6$  PFU ml<sup>-1</sup>.

+	HPUra-ultraviolet	25	4	0	0	1
—	HPUra-HPUra	11	6	1	0	6
Total		133	37	10	2	31

The SPO2 lysogen of *B. subtilis* 168 (*trp*<sup>-</sup>), CRK1000 (SPO2), was grown in Lp medium<sup>18</sup>, and treated with nitrosoguanidine (NTG) at 30 °C as before<sup>10</sup>. NTG-treated cells were washed and grown at 30 °C in minimal medium Cg (ref. 13) to minimise prophage induction after NTG treatment. After about 60 min cells began to increase when they were mixed with 20% glycerol and frozen in liquid nitrogen. Mutagenised cells were thawed immediately and grown in Lp medium at 30 °C for one generation. One sample (column 1) was plated directly on BHI agar<sup>10</sup> without further treatment. Other cells were heated to 45 °C, added to HPUra (70 µM) after 5 min and incubated for 60 min at 45 °C. Cells lysed at about 45 min. Surviving cells were collected by filtration, washed and then plated on BHI agar (column 2). In two samples (columns 3 and 4), survivals from the first HPUra treatment were grown in Lp medium at 30 °C and then heated to 45 °C. After 5 min at 45 °C cells were either added with HPUra (70 µM) or irradiated with ultraviolet light at 4 µW cm<sup>-2</sup> for 2 min. Cells were further incubated at 45 °C for 60 min and cells remaining after lysis were filtered, washed and plated on BHI agar. For the sample in the last column cells grown in Lp medium at 30 °C were used without NTG treatment. Cells plated on BHI agar plate after these various selections were grown at 30 °C and the colonies appearing after 12 h were replica plated on BHI and incubated at 45 °C. Colonies that failed to grow at 45 °C were isolated as *ts* mutants. *ts* lysogens thus obtained were grown in Lp medium at 30 °C and HPUra (70 µM) was added at an early exponential phase either at 30 °C or 5 min after heating to 45 °C. Cell lysis and phage production (detected by a spot test) were followed at both temperatures. The number of *ts* mutants that lysed and produced phage at 30 °C and did not lyse and produced few phages at 45 °C are listed. DNA was isolated from the HPUra-induced *ts* mutants (total 37) as described before<sup>18</sup>. Competent cells of CRK1500, *thy*<sup>-</sup>, *leu*<sup>-</sup>, were transformed with these DNA samples of saturated concentration<sup>18</sup>. From *leu*<sup>+</sup> transformants, *ts* transformants were selected and immunity to and infectivity by SPO2 were examined to confirm that the SPO2 genome was not co-transformed with *ts* markers. Of the 37 mutants, 31 were transformed successfully. The transformants (*ts*, *thy*<sup>-</sup>) were grown at 30 °C in the Lp medium containing <sup>3</sup>H-thymidine (0.5 µCi per 5 µg per ml) and DNA synthesis and growth were determined by <sup>3</sup>H-thymidine incorporation and turbidity measurement respectively, after heating the exponentially growing cell to 47 °C. In initiation mutants, the residual amount of DNA synthesis was 50–100%, equivalent to the DNA present at the time of heating. The same amount was less than 20–30% in the elongation mutants.

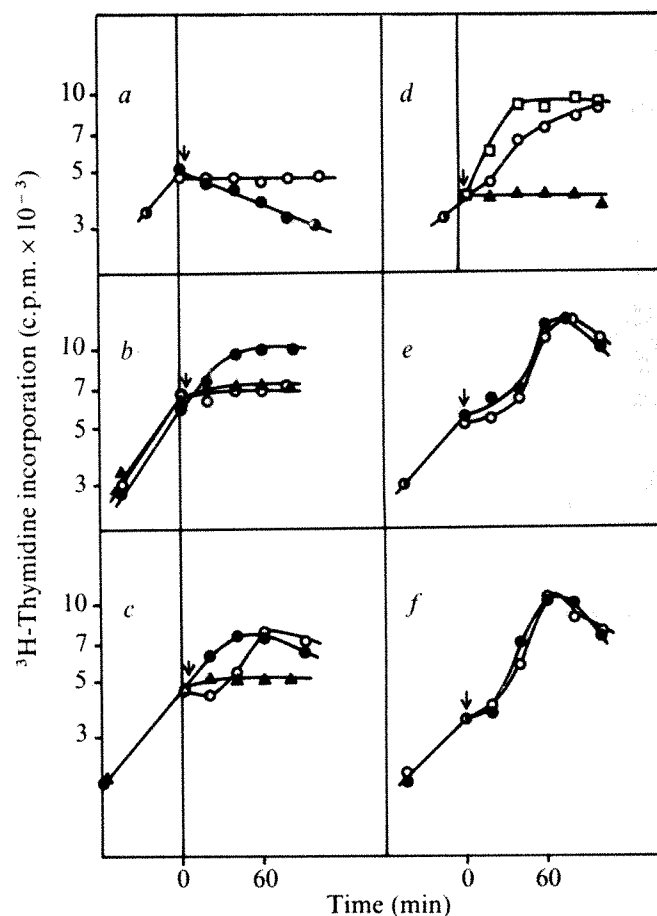

\* These include the mutants in which more than 100% of DNA was synthesised at 47 °C and those in which both DNA synthesis and growth were inhibited at 47 °C.

were found to be *dna-ts* initiation mutants. Marker frequency analysis during the incubation of these mutants at 47 °C clearly showed that the initiation of new rounds of replication was prevented immediately after heating (Fig. 1).

As expected, when these mutants were lysogenised with a wild-type SPO2 the prophage was induced by HPUra at 30 °C but not at 47 °C, as shown by cell lysis (Fig. 2), the phage titre liberated into the medium (legend to Fig. 2) and the incorporation of <sup>3</sup>H-thymidine in the presence of HPUra, which is a direct indication of the replication of the SPO2 DNA (Fig. 3). Data in Figs 2 and 3 show that (1) the sensitivity of chromosome replication to HPUra was not altered by the mutation, (2) the expression of early genes and the autonomous replication and maturation of SPO2 occurred normally at 47 °C in the presence of HPUra, as indicated by a successful infection by SPO2 and induction by mit C at 47 °C. Therefore we conclude that the change in the prophage from a repressed to a derepressed state caused by the cessation of chromosome replication by HPUra is prevented specifically at the non-permissive temperature.

From this evidence we conclude that the mutation in this group of *ts* mutants affects, at the non-permissive temperature, both the initiation of chromosome replication and the prophage induction by HPUra. We call them collectively *ts-dna-ind* mutants. No *ts-dna-ind* mutant was isolated when ultraviolet treatment was used at the second selection cycle in place of HPUra, and mit C

caused SPO2 induction in the mutants at 47 °C even in the presence of HPUra, indicating that ultraviolet light and mit C caused induction through a mechanism at least partly different from that of HPUra. These mutants carried a single mutation and the induction by HPUra occurred at 47 °C in *ts*<sup>+</sup> revertants. Furthermore, both initiation of chromosome replication and the induction of SPO2 by

**Fig. 3** Induction and infection of the phage SPO2 in *dna-ts* initiation mutants assayed by <sup>3</sup>H-thymidine incorporation in the presence of HPUra. Two *dna-ts* initiation mutants, CRK2605 and CRK2001, and their SPO2 lysogens were grown in complete Lps medium containing <sup>3</sup>H-thymidine (0.5 µCi per 5 µg per ml) at 30 °C. At an early exponential phase, cells were treated as shown below and DNA synthesis was measured as described in the legend to Fig. 1. □, Without drug; ○, with HPUra; ●, with mit C and HPUra; ▲, with HPUra and rifampicin. *a*, CRK2605; *b*, CRK2605(SPO2); *c*, CRK2001(SPO2); *d*, CRK2605. The cell was cultured at 30 °C and then the temperature of the culture was shifted quickly to 47 °C. After 5 min cells were added to the drugs and in (*d*) infected with the phage SPO2 (multiplicity of infection 0.6) simultaneously; *e*, CRK2605(SPO2) was cultured at 30 °C; *f*, CRK2001(SPO2) was cultured at 30 °C.

HPUra occurred when mutant cells (non-lysogen and SPO2 lysogen, respectively) were treated at 47 °C for 60 min and then cooled at 30 °C. Chromosome replication was re-initiated even in the presence of chloramphenicol, suggesting that the *ts* component was readily reactivated at 30 °C (data not shown).

Genetically it is interesting to ask whether these *dna-ind* mutations are clustered in one gene or dispersed in many genes. Recombination tests using two mutants carrying the *dna-ind* mutations as recipients revealed that the 10 *ts-dna-ind* mutations were not identical but closely linked, having recombination indices of 0–0.3, suggesting that they are located within one gene<sup>16</sup>. Furthermore, these mutations were tightly linked to *dna-ts27*, a mutation carried by a *ts-dna* initiation mutant isolated in our laboratory<sup>17</sup>. Phenotypes of the mutant with respect to the *ts* character of the initiation of the chromosome replication were indistinguishable from *dna-ind* mutations (Fig. 1). SPO2, however, was induced by HPUra in the *ts27* mutant even at 47 °C (Figs 2 and 3). These results suggest that the initiation of chromosome replication and prophage induction are affected independently by the *dna-ind* gene product. A single mutation in this gene may alter either one of the two functions or both functions simultaneously.

We assume that X has dual functions in the initiation of chromosome replication and prophage induction. This is suggested by the general resemblance between the two events in terms of their responses to bacterial growth rates. The highly selective concentration of the specific type of the *dna-ts* initiation mutant by the selection method used in this experiment revealed close relationship between the two events. Furthermore, the finding of the *dna-ind* gene and pleiotropic effects of its mutations support the existence of the suggested substance X. The relationship between the product of this gene and X is unclear at present but the simplest interpretation is that the product is X itself.

## Differentiation of B and T mouse lymphocytes in cell suspension and smears

THE differentiation of B and T lymphocytes by scanning electron microscopy and, in live suspensions, by light microscopy has led to controversy about their different surface characteristics<sup>1,2</sup>. They can be demonstrated serologically by the presence or absence of specific antigen markers in various animal species, including man. B cells can be re-

cognised among mouse lymphocytes by surface immunoglobulin staining under fluorescent microscopy<sup>4</sup>. The surface morphology of lymphocytes has been distinguished by light microscopy using Nomarski differential interference<sup>3</sup>. We have now used the Hoffman modulation contrast microscopy system<sup>6,7</sup> and confirmed that B and T lymphocytes have different surface characteristics. This technique makes it possible to observe both live cells and air-dried smears, and we have demonstrated the feasibility of restoring the distinct surface characteristics in blood smears.

C57BL/6, BALB/c and Dublin (ICR) Swiss mice, 4–8 weeks old, and of both sexes, were used. Peripheral blood was collected from the orbital sinus in 24 heparinised haematocrit tubes, and pooled in a syringe containing heparin (50 U). Pooled blood was layered on a Ficoll-Hypaque mixture for density gradient separation of lymphocytes and platelets by Boyum's method<sup>4</sup>. This layer was then removed and centrifuged at 400g and resuspended in Eagle's minimum essential medium (MEM) with or without 5% foetal calf serum (FCS).

Spleen and thymus from individual mice were pressed separately and gently through a stainless steel wire mesh in 5 ml of MEM with or without 5% FCS, followed by passage through a 26-gauge needle.

Fluorescein-conjugated anti-mouse IgM was obtained from Meloy Laboratories. Lymphocyte pellets obtained from a single spleen and thymus, or density-gradient-separated peripheral blood lymphocytes, were sedimented at 400g for 5 min and resuspended in 0.2 ml of MEM, then combined with 0.2 ml of the fluorescein-conjugated anti-serum at a protein concentration of 0.8 mg ml<sup>-1</sup>. The reaction mixture was incubated at 37 °C for 30 min with occasional shaking. Cells were washed three times in MEM only and resuspended in 1 ml of MEM containing FCS and applied to a microscope slide chamber made of two No. 1 glass coverslips mounted on the slide with Corning silicone vacuum grease. These supported a third coverslip, No. 1 1/2 thickness, making a thin chamber closed on two sides<sup>9</sup>. The chamber was filled by applying the cell suspension to one of the open sides, and inverted for 1–5 min to allow the cells to settle on the coverslip. When the chamber was reversed, many cells were hanging from the underside of the coverslip. Before examination, all cell suspensions were tested for cell viability by Trypan blue exclusion and found to contain more than 90% viable cells.

Peripheral blood obtained for the cell suspensions was also used for blood smears. Duplicate blood smears were

**Fig. 1** Thymus suspension from Dublin Swiss mouse showing the three types of surface characteristics of lymphocytes: villous (V), smooth (S), smooth, with a broad base surface difference (S<sub>b</sub>) (×40 achromat objective and ×10 ocular, Kodak 35-mm film No. 5032).

**Fig. 2** *a*, Spleen suspension from Dublin Swiss mouse tagged with fluorescein isothiocyanate anti-mouse IgM; crescent-shaped fluorescence from a villous lymphocyte, *b*, modulation contrast of same field. The arrow points to the same cell ( $\times 40$  achromat objective  $\times 3.3$  ocular, Polaroid film Type 107 and Kodak SO 410 35-mm film (inset)).

prepared from individual mice, one acted as a control slide stained with Wright's stain for differential white blood cell determination, the other for Hoffman modulation contrast visualisation. The unstained smear was processed within 24 h by immersion in physiological buffered saline at 20 °C for 30 s for red cells to lysis. A coverslip was then applied to the wet surface, excess fluid removed and the edges sealed with nail polish. Differential counts were made for lymphocytes, granulocytes and monocytes.

The Hoffman modulation contrast system was adapted to an ordinary Nikon bright-field transmission microscope, and to the Olympus reflected light fluorescent system on the Vanox transmission microscope by Modulation Optics Inc. The system involves a modulator placed off-centre in the back focal plane of the objective and an off-centre slit beneath the condenser. This creates intensity contrast of phase gradients, producing a three-dimensional image. The objective with the modulator is used with both reflected fluorescent and transmitted modulation contrast without degradation of the fluorescent image.

Suspensions of live lymphocytes from the peripheral blood, spleen and thymus of mice, examined with a  $\times 40$  achromat, objective, revealed two types of lymphocyte, some with fine, villous projections and others which were smaller, but with smooth surfaces (Fig. 1). There were also cells with essentially smooth surfaces, but which contained broad based projections (Fig. 1). When these suspensions were examined in the enclosed slide chamber for up to 1 h there was no essential change in their surface characteristics. Most lymphocytes in the lymphoid organ suspensions examined had smooth surfaces. Lymphocytes with villous

surfaces were fewer and varied in quantity with 0.2–2% in the thymus, an average of 13% in the peripheral blood and 23.2% in the spleen (Table 1).

Surface morphology of lymphocyte suspensions from the thymus incubated with fluorescein-conjugated anti-mouse IgM revealed less than 1% positive cells. When transmitted modulation contrast microscopy was directed to the same field of view, all fluorescent lymphocytes had villous surfaces. Less than 1% were villous and negative and all smooth lymphocytes were negative (Table 1).

Fluorescent cells revealed typical staining, with Ig limited to the surface in the form of a crescent or complete peripheral rim, or a stippled area. Specimens preincubated with unlabelled anti-mouse gamma globulin did not fluoresce when incubated with fluorescein-conjugated anti-IgM reagent. Suspensions of spleen and peripheral blood lymphocytes, which were observed but not counted, revealed similar patterns of fluorescence, although some villous lymphocytes did not fluoresce (Fig. 2).

**Fig. 3** Peripheral blood smear from C57BL/6 mouse, air-dried and restored. *a*, B lymphocyte with restored surface projections and serrated border; note background of lysed red blood cells. *b*, Smooth surface T lymphocyte with smooth border ( $\times 40$  achromat objective,  $\times 10$  ocular, Kodak SO 410 35-mm film).

**Table 1** Quantitation of lymphocytes with stated appearances as viewed by Hoffman modulation contrast microscopy

Organ cell suspension	Mouse	Smooth cells	Villous cells	% Villous cells

\*Non-fluorescent. †Fluorescent cells counted by reflected fluorescent and transmitted modulation contrast microscopy.

The characteristic leukocytes found in mouse blood smears were identified by modulation contrast as granulocytes, monocytes and lymphocytes. There was no appreciable loss of adherent leukocytes after a 30-s immersion in physiological buffered saline. Differential counts with standard Wright's stained slides revealed comparable differential counts with duplicate specimens differentiated for surface characteristics by modulation contrast microscopy (Table 2). The lymphocyte population included cells with small surface projections, closely grouped and extending from the peripheral borders, giving a serrated appearance (Fig. 3a), which were designated B cells. Other lymphocytes had smooth peri-

pheral borders and smooth surfaces, including some with one or two flattened projections or folds (Fig. 3b) and they were designated T lymphocytes. Counts of normal lymphocytes in each smear specimen gave a ratio of 89–92% of T cells and 8–11% of B cells (Table 2). The ratio of villous and smooth surface lymphocytes in the peripheral blood suspensions (average values of 13% and 87%) was similar with that of the restored blood smear preparations. This differentiation of T and B cells supports the observations of Rabellino *et al.*<sup>4</sup>. Similar surface differences have been revealed by Nomarski interference contrast on unfixed human<sup>10</sup> and guinea pig<sup>3</sup> lymphocyte suspensions.

We cannot reconcile our observations with those of Alexander and Wetzel<sup>2</sup>, who found no differentiation of villous and smooth cells among mouse and human lymphocyte populations prepared for scanning electron microscopy. They showed that the smooth lymphocyte population observed by scanning electron microscopy by Polliak *et al.*<sup>1</sup> may have resulted because fixation smoothed the surface structures nonspecifically. Our observations on living cell suspensions indicate no surface changes on smooth or villous surfaces during up to 1 h.

**Table 2** Comparison of leukocyte count in Wright-stained and modulation contrast microscopy of blood smears of mice

G, Granulocytes; M, monocytes; T, T lymphocytes; B, B lymphocytes.

In all cases the anti-mouse IgM fluorescent stain selected cells with villous projections, whereas if the environment changed the villous cells to smooth cells, the stain would have been expected among the smooth population. Some villous lymphocytes did not fluoresce, perhaps because the IgM antiserum was not specific for those surfaces: another heavy chain gamma globulin fraction of antiserum could be reactive.

Although with restored preparations it was possible to distinguish B and T lymphocytes, villous projections were shorter and less distinct. Conditions for viewing smears are optimal when preparations are restored within 24 h at room temperature. Optimal physical conditions for maintaining dried smears have not been explored fully.

This work was supported in part by grants from the Inter-Boro Leukemia Organization and the Friendship Fund, Inc. Modulation Optics, Inc. supplied the modified objectives and condensers. I thank Dr Robert Hoffman for help and Roger Gradess and Mark Friedman for technical assistance.

## Inhibitory effect of dibutyl cyclic AMP and theophylline on the aggregation of human breast tumour cell line BT-20

DISSOCIATED cells from embryos are able to reaggregate to form multicellular structures resembling those of the original tissue<sup>1,2</sup>, this ability being inversely proportional to the age of the embryo<sup>1,3</sup> or to the age of the cells in tissue culture<sup>4</sup>. This intracellular adhesion is tissue specific, and is believed to have a key role in growth and morphological differentiation<sup>5</sup>. It has also been noted that many tumour cell lines can reaggregate in the same condition as embryonic cells<sup>6–10</sup>. Leighton has observed the formation of small aggregates when tumour cells were grown in cellulose sponge<sup>11</sup>. He directs attention to the fact that many clinical carcinomas appear as aggregates or nests of cells, and suggests that factors intrinsic to the formation of aggregates are involved in the spread of cancer.

It has been shown that cyclic AMP may influence factors of the cellular membrane such as concanavalin A (con A) agglutination<sup>12</sup>, surface antigens on cells<sup>13</sup>, morphology of cells<sup>14</sup>, contact inhibition of growth<sup>15</sup>, and adhesion of cells to glass<sup>16,17</sup>. We report here that dibutyl (db) cyclic AMP and theophylline inhibit the aggregation of human mammary tumour cell line BT-20 (ref. 18).

The method of aggregating the cells is essentially that of Moscona<sup>1</sup>. BT-20 cells were grown in the medium RPMI 1640, with 10% foetal calf serum and 20  $\mu\text{g ml}^{-1}$  of insulin added. Suspensions of single cells were prepared from confluent cultures by trypsin and EDTA. Aliquots of cell suspensions (3 ml) containing  $10^4$ – $2 \times 10^6$  cells  $\text{ml}^{-1}$  were placed in 25-ml Erlenmeyer flasks and shaken on a gyrotary shaker for 24 h at 37 °C at 72 r.p.m., with a radius of rotation of 1.25 cm. The cells were washed twice in serum-free medium and then suspended in RPMI 1640 buffered with 20 mM HEPES to give the desired cell density. Serum and insulin were omitted from the medium during experiments, except where the effect of serum was studied. Stock solutions of db cyclic AMP (10 mM), cyclic AMP (10 mM), theophylline

**Fig. 1** Effect of cell density on aggregation size of BT-20 cells. Single cell suspensions at  $1.25 \times 10^4$  to  $2 \times 10^6$  cells  $\text{ml}^{-1}$  in RPMI medium without serum were placed in 25-ml Erlenmeyer flasks in 3-ml aliquots. The cell suspensions were incubated in a gyrotary shaker at 72 r.p.m. for 24 h. Samples (0.5 ml) were removed from each flask and placed in a plastic Petri dish. Photomicrographs of the aggregates were taken and the diameter of the aggregates measured. The mean size of aggregates from four flasks is shown here.

Fig. 2 Photomicrographs of aggregates made from a suspension of cell density  $0.5 \times 10^6$  cells  $\text{ml}^{-1}$ . *a*, Control aggregates; *b*, in the presence of 1 mM db cyclic AMP and 1 mM theophylline. Bar, 200  $\mu\text{m}$ .

(10 mM) or papaverine (1 mM) were each made up in RPMI 1640. The size of the aggregates was measured by placing 0.5 ml of the suspension in a 35-mm plastic Petri dish, and photographs of the aggregates taken. The negative was then projected through an enlarger at a fixed distance. The outlines of the aggregates were traced on to paper and the size of each aggregate measured by comparing with standard metric circle and ellipse templates. The results were then expressed in  $\mu\text{m}$  diameter of cross section of the aggregates. About 300 aggregates were analysed for each determination.

The aggregation of BT-20 over a 24-h period depended on the number of cells present in the incubation. Figure 1 shows that the mean size of aggregates obtained was maximum at about  $0.5 \times 10^6$ – $1.0 \times 10^6$  cells  $\text{ml}^{-1}$ . A 0.5 ml volume of a suspension of this cell density yielded a reasonable number of discrete aggregates for measurement. In the presence of 10% serum the aggregates were slightly larger, but many more cells adhered to glass. Occasionally a thick cord of cells detached from the glass making measurements difficult. Using a standard density of  $5 \times 10^5$ – $10^6$  cells  $\text{ml}^{-1}$ , we found that the addition of 2 mM db cyclic AMP and 2 mM theophylline greatly inhibited the aggregation of BT-20 cells. Figure 2*a* is a photomicrograph of the control aggregates, and Fig. 2*b* shows aggregates obtained in the presence of db cyclic AMP and theophylline. In Fig. 3*a* we present histograms of aggregate size in the control and treated cultures. The figures show that db cyclic AMP and theophylline restricted the diameters of aggregates to less than 25  $\mu\text{m}$ . In Table 1 we show the percentage of aggregates with diameters  $\geq 25 \mu\text{m}$  in the control and treated incubations. After 24 h, db cyclic AMP and theophylline inhibited reaggregation by a factor greater than 4.

The inhibitory effect of db cyclic AMP and theophylline was reversible. After removal of the drugs, the cells and aggregates were washed three times with 10 ml of medium, resuspended in 3 ml of medium, and then incubated on the gyrotary shaker. Comparison of Fig. 3*b* (48-h aggregates) with Fig. 3*a* (24-h aggregates) shows that after the further 24-h incubation there were many more large aggregates and the distribution of the size of aggregates was comparable with that of the control at 24 h. The control aggregates after 48 h of incubation also increased in size as shown in Fig. 3*b*. In another experiment, similar results were obtained when aggregates from treated incubations were washed and trypsinised to yield suspensions of single cells. These cells reaggregated to the same extent as the control cells.

To ascertain that db cyclic AMP and theophylline did not kill BT-20 cells, we carried out the Trypan blue exclusion test after 24 h of incubation. Both treated and control incubations showed the same degree of cell viability ( $>90\%$ ). Single cells and aggregates in treated incubations also attached to glass and spread out after removal of the drugs and reincubation without shaking. The inhibitory effect of db cyclic AMP and theophylline was dependent on concentration. Figure 4 shows the increasing degree of inhibition with increasing concentration of drugs. It is possible that db cyclic AMP was hydrolysed by the cells to butyrate, which has been shown to produce a similar effect on cells as cyclic AMP<sup>19</sup>. We tested the effect of sodium butyrate on BT-20 aggregation, and found that 2 mM butyrate was highly toxic to cells. At a concentration of 0.5 mM, however, toxicity was not detected and there was no effect on cell aggregation. The compound cyclic AMP alone also inhibited aggregation, but a much higher concentration (5–10 mM) was necessary.

Fig. 3 Histograms showing the effect of db cyclic AMP and theophylline on aggregation of BT-20 cells. *a*, 24-h incubation. Open bars, control aggregates; shaded bars, aggregates treated with db cyclic AMP and theophylline. *b*, 48-h incubation. After the first 24-h incubation the aggregates were collected, spun down, washed, and resuspended in RPMI medium without serum or drugs for the second 24-h incubation. Open bars, control aggregates; shaded bars, aggregates treated with db cyclic AMP and theophylline for 24 h and recovery after removal of the drugs.

**Table 1** Inhibitory effect of db cyclic AMP and theophylline on aggregation of BT-20 cells

	Control	db cyclic AMP + theophylline	Control	Recovery*
	24 h	24 h	48 h	48 h
Aggregates with diameters ≥ 25 µm	46.2	10.7	80.6	66.1

Results are expressed as the percentage of aggregates greater or equal to 25 µm diameter in relation to the total number of aggregates measured.

\*After treatment for 24 h with db cyclic AMP and theophylline, the cells were centrifuged, washed three times with 10 ml of medium, and then resuspended in 3 ml of medium. The aggregates were measured 24 h later.

The compound db cyclic AMP has been shown to be more resistant than cyclic AMP to hydrolysis by phosphodiesterase<sup>20</sup>. We have further tested the effect of theophylline alone on reaggregation, and found that it was almost as effective as the combination of db cyclic AMP and theophylline. Of the other phosphodiesterase inhibitors, we have tested papaverine and trifluoperazine. The latter was very toxic to BT-20 cells at 50 µM. At 20 µM, however, toxicity was not apparent and there was no effect on aggregation. Papaverine, on the other hand, was well tolerated by BT-20 cells. At 100 µM it produced 70–80% inhibition of aggregation without toxicity. (A detailed report on the effect of papaverine on cell–glass and cell–cell adhesion is in preparation.)

The phenomenon of cell aggregation may involve several steps. Orr and Roseman<sup>21</sup> have found that the initial intercellular adhesion of embryonic chick neural retina cells was not affected by cyclic AMP, but Kuroda<sup>22</sup> found that cyclic AMP during 24 h of incubation inhibited the aggregation of embryonic neural retina cells. We have shown in this series of experiments that cyclic AMP and some inhibitors of phosphodiesterase inhibited aggregation of BT-20 cells in suspension. A number of investigators<sup>23–25</sup> have observed that cellular junctions, such as desmosomes, form in aggregates. Some preliminary electron microscopic studies on BT-20 aggregates also showed the formation of desmosomes after 24 h of incubation. We are pursuing the investigation to see if cyclic AMP inhibits the formation of desmosomes.

Several studies<sup>10, 26–29</sup> indicate that aggregation-promoting factors of a glycoprotein nature are involved in a number of systems from sponge cells to rat hepatoma cells. Since

cyclic AMP can influence a number of cell surface activities, it is conceivable that its inhibitory effect on cell aggregation is due to a change in the orientation of these 'aggregation molecules' by an alteration of membrane fluidity, or a direct effect on the biosynthesis of these molecules.

The inhibitory effect of cyclic AMP on membrane activities of human cells has also been noted by Bryant and Sutcliffe<sup>30</sup>, who found that high concentrations of intracellular cyclic AMP inhibited the adhesiveness of human basophils, eosinophils, and neutrophils. Increasing the concentration of cyclic AMP level also inhibits human platelet aggregation<sup>31</sup>.

Our experiments suggest that cyclic AMP, by its modulation of adhesion between carcinoma cells as they form aggregates, may have a role in the propagation of cancer<sup>32</sup>.

This investigation was supported by a contract from the National Institutes of Health.

**Fig. 4** Effect of varying concentrations of db cyclic AMP and theophylline on aggregation of BT-20 cells, which were incubated in 3 ml of medium on a gyrotary shaker. The medium contains db cyclic AMP and theophylline at various concentrations. The sizes of aggregates at 24 h were measured.

## Abortogenic activity of antiserum to alpha-foetoprotein

ALPHA-FOETOPROTEIN (AFP), a glycoprotein of molecular weight 70–72,000, is synthesised by the yolk sac and by perivascular parenchymal cells of the mammalian foetal liver and gastrointestinal tract<sup>1–3</sup>. Increased levels of AFP occur in maternal and foetal sera during pregnancy<sup>4,5</sup>, and indirect evidence suggests some production of AFP by the chorionic tissues<sup>6</sup>. Increase of AFP in amniotic fluid has been correlated with neural tube defects, anencephaly, hydrocephaly, congenital nephrosis and foetal death<sup>7–10</sup>. The specific function of AFP has not been determined, but oestrogen-binding and immunoregulation during pregnancy have been implicated<sup>11,12</sup>. Smith<sup>13</sup> noted an effect of rabbit antiserum to rat AFP when injected into pregnant rats. We now report evidence for a specific abortogenic activity

of rabbit antiserum to murine AFP (anti-AFP) when administered during gestation in the laboratory mouse.

Approximately 100 pregnant mice (day 9–20 of gestation) of the DB2A, C57BL, or Nya:NYLAR strains were injected intraperitoneally with 0.5–2.0 ml of specific anti-AFP (prepared as described under Table 1), with non-immune rabbit serum (NRS), or with buffered saline. The mice were examined 6, 12, 18 and 24 h after injection, and the cages were inspected for aborted fetuses. At 24 h, the mothers were autopsied; the litter size and foetal dimensions were determined. Foetuses and neonates from mothers in all treatment groups were examined for gross morphological changes. Histological sections of the foetal and maternal tissues were prepared using Bouin's fixation and haematoxylin and eosin. The uteri with implantation sites were examined in multiple sections. Samples of maternal liver, ovary, lung, spleen and kidney were examined routinely.

Three levels of response were noted: no effect; partial abortion indicated by subplacental haemorrhage; and complete abortion. Passage of aborted foetuses usually occurred 16–20 h after injection. Anaphylaxis was rarely observed. Of the animals treated with specific anti-AFP, 68% exhibited a physiological response (Table 1). Partial and complete abortions both occurred in the latter two thirds of gestation. Partial abortions tended to occur earlier and complete abortions slightly later. As a rule, the greater the

foetal mass, the more anti-AFP was needed to produce the response. During mid-pregnancy 0.5–1.0 ml of intra-peritoneally administered anti-AFP was sufficient to produce abortion. Towards the end of pregnancy, induction of abortion was less frequently successful and required up to 2.0 ml of anti-AFP.

Gitlin and Koch<sup>17</sup> showed that heterologous IgG readily passes through the placenta in the mouse by both first and second order reactions. Thus, the passage of rabbit anti-AFP antibodies across the mouse placenta is likely. In the pregnant rat, Sell *et al.*<sup>18</sup> and Colquhoun *et al.*<sup>19</sup> reported a steep increase of AFP in maternal serum beginning at days 10–14 and continuing to birth. Sell and Alexander<sup>20</sup> further demonstrated that a catabolic site for AFP is present in the foetus or placenta during the last week of gestation in the rat. These studies indicated that increasing amounts of AFP traverse the placenta as development proceeds. A similar increase of AFP levels in late pregnancy in mice could account for a neutralisation of anti-AFP antibodies at the doses we tested.

The difference in response levels of the three treatment groups was significant by  $\chi^2$  analysis ( $P < 1.0\%$ ). None of the animals injected with buffered saline exhibited physiological or pathological effects. More than 90% of the mice treated with NRS also showed no effect. In the three animals aborted by NRS, the effect occurred on days 15 and 16. This suggested a nonspecific susceptibility of the uterus to extrinsic factors at this time.

To confirm the specificity of the anti-AFP effect, we tested rabbit antisera to whole mouse serum and to three mouse protein antigens that are similar to AFP in either structure or site of origin: albumin, complement (C3) and transferrin<sup>21</sup>. These antisera caused neither partial nor complete abortion in any animal tested (Table 1). As a further test of specificity, aliquots of anti-AFP for injection were absorbed individually with freshly prepared pregnant uterine tissue extracts or with purified AFP fractions obtained from column fractionation. The tissue saline extracts were prepared according to Witebsky's<sup>22</sup> method. Serum specificity was tested by blocking experiments, using both purified AFP antigen and tissue (uterus and spleen) absorption. The tissues from six pregnant mice (13–18 d gestation) were homogenised in phosphate-buffered saline (pH 7.6) and the resultant tissue brei was absorbed in equal proportions (w/v) with the antisera for 30 min at 37 °C, then overnight at 4 °C. Precipitation-inhibition results were confirmed by immunodiffusion. With two exceptions the absorbed antisera produced no effect when injected into pregnant mice at days 13–16 of gestation. Anti-AFP absorbed with a murine spleen tissue extract retained abortogenic activity, and anti-AFP absorbed with one of three uterine tissue samples caused an anaphylactic response.

The mechanism of pregnancy interruption by anti-AFP is unknown, although the specificity of the reaction is evidenced by target tissue absorption and by the lack of effect of rabbit antisera to other mouse serum proteins. Except for intrauterine clot formation, histopathological studies were unrevealing. There seemed to be no inflammatory or lymphocytic infiltrates in the decidua or placenta, and vasculitis was not observed in any tissue. Although studies by Smith<sup>13</sup> demonstrated that the injection of pregnant rats with anti-AFP serum may also result in developmental abnormalities, none was observed in autopsied or surviving litters of any of the mice we treated.

The abortogenic activity of anti-AFP may be due to an anaphylactoid contraction of the uterine smooth muscle; that is, the response may be an *in vivo* correlate of the Schultz-Dale reaction<sup>23</sup>. This humoral mechanism would require the presence of AFP in the uterine or placental tissues. The demonstration by Michel *et al.*<sup>24</sup> of AFP receptors in the immature rat uterus provides some support for this hypothesis.

**Table 1** Response of pregnant mice to intraperitoneally injected rabbit anti-AFP, non-immune rabbit sera (NRS), physiological saline or rabbit antisera to other mouse serum proteins

Treatment group	Response	No. animals	Gestational age (d)* Range	Mode
Anti-AFP	Complete abortion	11/31	12–17	15
	Partial abortion	10/31	9–14	13
	No effect	10/31	14–20	18
NRS	Complete abortion	3/36	15–16	15
	No effect	33/36	9–20	15
Saline	No effect	16/16	9–20	17
Anti-transferrin	No effect	4/4	15–18	17
Anti-complement	No effect	4/4	14–17	15
Anti-albumin	No effect	6/6	12–15	15
Anti-whole mouse sera	No effect	6/6	11–18	14

Rabbit antiserum to murine AFP (anti-AFP) was produced by immunisation with antigen fractions derived from amniotic fluid<sup>14</sup>. The AFP was isolated by gel filtration on Sephadex G-75, followed by shallow-gradient DEAE ion exchange chromatography and preparative gel electrophoresis<sup>15</sup>. Disc gel electrophoresis showed a single band, and after immunoelectrophoresis a single precipitin arc was present in the  $\alpha$ -1 region. In spite of these indications of purity, albumin was detected as a trace contaminant after immunisation and was eliminated by absorption using two parts normal mouse sera to eight parts antiserum. The absorbed anti-AFP was immunoreactive to mouse AFP as evidenced by single-band formation after immunodiffusion and counterimmunoelectrophoresis. Anti-AFP from four rabbits were used. These antisera had specific antibody concentrations of 0.424–0.532 mg ml<sup>-1</sup> as determined by the quantitative precipitin reaction. Each anti-AFP serum was tested at all stages of pregnancy in separate experiments. The results included in Table 1 summarise all these data. Control sera consisted of non-immune rabbit serum (NRS), rabbit anti-whole mouse sera, rabbit anti-mouse albumin, rabbit anti-mouse transferrin and rabbit anti-mouse complement. The NRS serum was absorbed with mouse sera as described above. The anti-albumin serum was prepared from mouse albumin isolated by ion exchange chromatography; the antisera to whole mouse sera, transferrin and complement were obtained from Microbiological Associates. The specificity of these control sera was confirmed both by immunoelectrophoresis and immunodiffusion using whole and fractionated mouse serum. The immunological activity of each of the four anti-AFP and of the control antisera was attributed to the IgG, as determined by immunoelectrophoresis. The anti-AFP and anti-albumin sera were obtained from hyper-immunised rabbits bled 6 weeks after the first injection thus assuring a predominance of IgG antibody in the serum.

\*Length of gestation at time of injection. Gestational age was estimated by palpation, and foetal size was determined by crown-rump measurements according to Rugh<sup>16</sup>.

An alternative possibility is suggested by the work of Murgita and Tomasi<sup>22,25</sup>, who demonstrated that AFP suppresses both the primary and secondary antibody response to sheep red blood cells without inducing cytotoxic effects *in vitro*. Further studies by Murgita and Tomasi revealed that AFP can suppress allogeneic and mitogen-induced lymphocyte transformations (T-cell dependent functions) in mice<sup>25</sup>. Finally, immunofluorescence studies by Dattwyler *et al.*<sup>26</sup> strongly suggest the presence of AFP receptors on the surface of certain T-cell lymphocyte populations in mice. On the basis of these findings, it can be postulated that AFP is instrumental in maintaining pregnancy, the foetus being viewed as an allograft in the maternal tissues. Extrapolating this hypothesis, neutralisation of AFP at the maternal-placental interface might conceivably initiate rejection of the foetus through a cell-mediated immune mechanism. Although evidence of a graft (foetus) rejection was not histologically apparent, the physiological release by lymphocytes of vasoactive lymphokines, such as prostaglandins<sup>27</sup>, and/or the release of T-cell suppressor function might not necessarily leave a morphological trace.

## Early production of intracellular IgM by B-lymphocyte precursors in mouse

IN BALB/c mice, surface immunoglobulin (Ig)-bearing B lymphocytes are first detectable by immunofluorescence at 17 d gestation in the liver and spleen<sup>1</sup>. Explants of 14-d foetal liver<sup>1</sup> and spleen<sup>2</sup>, and 15-d bone marrow (our unpublished observations), have been shown to generate Ig-bearing B cells *in vitro* after 4-7 d of culture, suggesting that B lymphocytes normally develop multifocally in the haemopoietic tissues of mice. We have used direct immunofluorescence to demonstrate cells with intracellular IgM and no detectable surface Ig in mouse foetal liver as early as 12 d gestation. Our results suggest that B lymphocyte precursors synthesise IgM several days before they incorporate these molecules into their plasma membranes as cell-surface receptors for antigen.

Purified goat antibodies to mouse  $\kappa$  chains (anti- $\kappa$ ),  $\mu$  chains (anti- $\mu$ ),  $\alpha$  chains (anti- $\alpha$ ) and  $\gamma 2a$  and  $\gamma 2b$  chains (anti- $\gamma 2$ ) were raised, adsorbed and purified on various immunoadsor-

bants, and tested for specificity, as previously described<sup>3-5</sup>. While the anti- $\gamma 2$  antibodies used in our original experiments on the development of B cells in foetal liver explants<sup>1</sup> were subsequently found to have contaminating antibodies against  $\kappa$  chains (probably accounting for most, and possibly all, of the apparent  $\gamma 2$ -bearing cells seen), the anti- $\gamma 2$  (as well as the anti- $\mu$  and anti- $\alpha$ ) antibodies used in the experiments reported here could not be demonstrated to have any anti- $\kappa$  activity, and were class specific by Ouchterlony analysis, immunofluorescence staining of fixed cell preparations of various mouse myelomas, and modulation experiments in which each antibody preparation did not modulate surface Ig of other classes at a concentration of 1 mg ml<sup>-1</sup>. The purified antibodies were conjugated to fluorescein or rhodamine as previously described<sup>3,4</sup>. In some experiments purified polyspecific goat anti-mouse Ig conjugated to fluorescein (anti-MIg-FI) was used<sup>6</sup>. Nonspecific staining of fixed cells was eliminated by adsorbing the conjugates with mouse liver powder. The conjugated antibodies were used at a final concentration of 500  $\mu$ g ml<sup>-1</sup>.

\*Cells were stained in suspension with anti- $\mu$ -Rd to label surface IgM and with anti- $\mu$ -FI (after cytocentrifugation and fixation) to label intracellular IgM. As discussed in the text, surface IgM<sup>+</sup> cells stained with both rhodamine and fluorescein conjugates while intracellular IgM<sup>+</sup>/surface IgM<sup>-</sup> cells stained only with fluorescein. Usually, more than 50,000 cells were scanned.

†Each number represents one experiment.

‡These cells also failed to show surface labelling with polyspecific anti-MIg, suggesting the lack of any detectable surface Ig.

Haemopoietic and lymphoid tissues were removed from BALB/c embryos of various ages (the day of appearance of a vaginal plug being taken as day 0), newborns or 6-week-old adults, and dissociated into single cell suspension in Dulbecco's modified Eagle's medium containing 15 mM HEPES, 0.2% sodium azide and 10% foetal calf serum (DMEM). The cells were labelled in suspension with rhodamine-conjugated anti-Ig antibodies at 0 °C for 30 min to demonstrate surface Ig, washed and cytocentrifuged onto a glass slide, fixed in cold 5% acetic acid in ethanol, and stained for intracellular IgM with fluorescein-conjugated anti-Ig antibodies at 37 °C for 25 min. After thorough washing, the cells were examined under a coverslip for surface (rhodamine) and intracellular (fluorescein) fluorescence, using a Zeiss Ultraphot II, or a Leitz Ortholux microscope, equipped with phase contrast and incidence fluorescence optics and an Osram HBO 200 mercury arc lamp. Fluorescein-conjugated anti-Ig antibodies for surface staining and rhodamine conjugates for intracellular staining gave the same results.

As has previously been reported<sup>1</sup>, cells in foetal liver with detectable IgM on their surface were first seen at 17 d gestation (Table 1). But foetal liver cells with readily detectable intracellular IgM and without detectable surface Ig were first seen at 12 d in some mice and by 15 d in all litters studied (Fig. 1). Although most of these cells were large (comparable in size with medium or large lymphocytes), some were the size of small lymphocytes. The staining of fixed cells with fluoresceinated-anti- $\kappa$  antibodies (anti- $\kappa$ -FI) gave similar results to those obtained with anti- $\mu$ -FI, but no intracellular labelling was seen with anti- $\gamma 2$ -FI or anti- $\alpha$ -FI. This attested to the specificity of the intracellular labelling with anti- $\mu$ -FI and anti- $\kappa$ -FI, and indicated that these intracellular IgM<sup>+</sup>/surface Ig<sup>-</sup> cells

**Fig. 1** *a*, Cell stained for intracellular IgM with anti- $\mu$ -Rd in 15-d foetal liver; *b*, For comparison, a plasma cell in adult spleen stained for intracellular IgM with anti- $\mu$ -Rd. The film was exposed for 3.5 min in *a* and 2 s in *b* ( $\times 300$ ).

produced both heavy ( $\mu$ ) and light Ig chains. Nonspecific labelling due to binding to Fc receptors was also excluded by showing that  $F(ab')_2$  fragments of anti- $\mu$  antibodies, conjugated to fluorescein, gave results similar to those obtained with undigested anti- $\mu$ -Fl.

To detect intracellular Ig, cells must be fixed before labelling, while cell surface Ig can be demonstrated by labelling either living cells in suspension or cells fixed on a slide. Thus, cells with surface Ig (B cells) stained with both fluorescein and rhodamine in our double labelling technique, whether or not they had detectable intracellular Ig. Therefore, to determine whether these cells also had detectable intracellular Ig, we labelled surface IgM on living adult spleen cells with anti- $\mu$ -Rd in capping conditions<sup>7</sup> (DMEM without azide for 20 min at 20 °C) and then looked for intracellular IgM with anti- $\mu$ -Fl, after fixation. All the fluorescein labelling coincided with the rhodamine labelling in the caps and was not seen elsewhere in the cell, indicating that most surface-IgM<sup>+</sup> cells in spleen did not have intracellular IgM detectable by this means. In a similar experiment with newborn liver cells, a small proportion of the surface IgM<sup>+</sup> cells also showed intracellular IgM.

As Table 2 shows, intracellular IgM<sup>+</sup>/surface Ig<sup>+</sup> cells were found only at sites of B lymphocyte production, such as foetal and newborn liver<sup>1</sup> and spleen<sup>2</sup> and adult bone marrow<sup>7,9</sup>. They were not found in adult lymph node or spleen, or in foetal thymus. Their distribution, and the fact that they synthesise Ig, strongly suggest that they are B lymphocyte precursors, and we will refer to them subsequently as pre-B cells. IgM-containing plasma cells and other IgM-secreting lymphoid cells in adult lymphoid tissues, were readily distinguished from pre-B cells because the former stained much more intensely with anti- $\mu$ -Fl (Fig. 1) and always had readily detectable IgM on their surface. Table 2 shows that most IgM-synthesising cells in foetal and newborn liver and spleen, and in adult bone marrow are pre-B cells rather than B cells. Since they appear several days earlier in ontogeny than do B cells with surface Ig, one should be able to use fluorochrome-labelled antigens to study the generation

of antibody diversity earlier than previously possible. In addition, having an intracellular marker for pre-B cells should be useful for studying B-cell development in normal and immunodeficient animals, including man.

The pre-B cells in adult bone marrow described here presumably are the same as, or overlap considerably with, the surface Ig<sup>+</sup> cells, previously described in bone marrow, which can differentiate into surface Ig<sup>+</sup> B cells *in vitro* and *in vivo*<sup>8,9</sup>. Our failure to detect significant numbers of pre-B cells in the adult spleen suggests that this organ is not an important site where pre-B cells differentiate to B cells in adult animals, and that most "null cells" (cells lacking T or B cell surface markers)<sup>6,10</sup> in the spleen probably do not belong to the B-cell lineage. It also seems likely that our pre-B cells in foetal liver are among the "Type 1 B cells" described by Melchers *et al.*<sup>11</sup> as large cells in 10–12-d mouse embryos and in 13–15-d foetal liver and in adult bone marrow, which incorporate radioactive leucine into rapidly turning over ( $T_{1/2}$  = 1–3 h) 7–8S IgM. Since such 7–8S IgM could be labelled by lactoperoxidase-catalysed radioiodination of adult bone marrow cells, Melchers *et al.* suggested that it is on the cell surface, and that the failure of others to demonstrate it there may be due to its rapid turnover<sup>11</sup>. This is an important question, as the presence or absence of Ig at the cell surface would determine whether or not such cells could bind, and possibly respond to antigen.

**Table 3** IgM<sup>+</sup> cells in foetal liver explants inhibited with anti- $\mu$  antibody

Age of liver (d)	Days in culture	Anti- $\mu$ in culture ( $\mu$ g ml <sup>-1</sup> )	Surface IgM <sup>+</sup> cells (%)	Intracellular IgM <sup>+</sup> /surface IgM <sup>+</sup> cells (%)
18	3	0	1.8	2.9
18	3	20	0	3.2
14	7	0	7.4	9.5
14	7	20	0	7.2

To help resolve this apparent discrepancy, we cultured foetal liver fragments on top of Millipore filters as described previously<sup>1</sup> in the presence or absence of unconjugated anti- $\mu$  antibodies (20  $\mu$ g ml<sup>-1</sup>). We have shown previously that anti- $\mu$  antibodies in such cultures induce the disappearance (and prevent the development) of cell-surface IgM<sup>5</sup>. As Table 3 shows, although no surface IgM was found on anti- $\mu$  treated cells this treatment did not affect the proportion of cells with intracellular IgM or the intensity of their staining. Thus most of the IgM that we have detected as intracellular in pre-B cells by our double labelling technique seems not to be available at the cell surface, and unlike B cells<sup>5</sup>, these cells are not killed or suppressed by prolonged exposure to anti-Ig antibodies. These experiments do not exclude the possibility that a small proportion of the IgM synthesised by these cells is exposed at the cell surface.

The biological significance of the intracellular IgM in pre-B cells is enigmatic. It seems more likely that it is destined for the plasma membrane than for secretion, but then it is not clear why there is such a long period between synthesis and incorporation into the cell surface. It may be that it provides a mechanism for protecting these cells from interacting with antigen during a period of clonal expansion and/or diversification of activated V genes. If the IgM is destined for the plasma membrane, the failure to find detectable intracellular IgM in B cells with surface IgM, suggests that it may accumulate in pre-B cells because it cannot get to, or be stably incorporated into, the plasma membrane. Perhaps, this incorporation must await the production of an appropriate glycosyl-transferase, proteolytic enzyme, or cell-surface acceptor protein. Whatever the explanation, these cells may provide a useful system for studying where membrane proteins are made and how they are distributed to their appropriate location in the cell.

We thank Mrs L. Minto and W. E. Gathings for technical

## Resistance of activated macrophages to H-2 antibody-mediated cytotoxicity and Fc rosette inhibition

MACROPHAGES can have critical roles in repair, inflammation and a large variety of immunological phenomena<sup>1,2</sup>. The biological roles of these cells often occur subsequent to their 'activation', a subjective term which refers to a greatly heightened state of reactivity<sup>1-3</sup>. Activation can be induced by a variety of stimuli including ingestion of certain macro-organisms, contact with immune complexes, bacterial lipopolysaccharides and lymphokines<sup>3</sup>. Activated macrophages usually show an increase in cell size, increased adherence properties and cellular processes, lysosomal enzyme activity, and phagocytic ability<sup>1,2</sup>. In addition, alteration in characteristics and functions of various macrophage receptors can apparently take place as a consequence of activation<sup>4,5</sup>. Such a change is described in this paper: it involves Fc receptors as detected by Fc or EA rosette formation (see Table 1), and their relationship to surface mouse major histocompatibility (H-2) antigens as detected by anti-H-2 alloantisera. Aside from the general relevance this change has with regard to membrane alterations which occur in activated lymphoreticular cells, it can also be exploited as a marker for activated macrophages.

Recent results have shown that formation of Fc (EA) rosettes between IgG antibody-coated erythrocytes and lymphoid cells bearing Fc receptors can be totally blocked by preincubation of the lymphoid cells with relevant anti-erythrocyte against the major histocompatibility antigen complex<sup>6,7</sup>. An example of this is seen in Table 1: preincubation of DBA/2 (H-2<sup>d</sup>) mouse strain spleen cells with anti-H-2<sup>d</sup> alloantisera resulted in a marked reduction of the ability of the cells to subsequently form Fc rosettes with IgG antibody-coated sheep erythrocytes (SRBCs) compared with normal mouse serum (NMS)-treated controls. Preincubation with irrelevant anti-H-2 serum (for example anti-H-2<sup>b</sup>) resulted in no inhibition. When normal peritoneal exudate cells (PECs), containing an average of about 24% macrophages (assessed by ingestion of latex particles) were

similarly tested, rather drastic inhibition in the ability of the cells to form Fc rosettes was once again noted. Since macrophages bear the Fc receptor<sup>1,4</sup>, these results show that the Fc rosetting ability of most or all normal (unstimulated) macrophages is inhibited by the anti-H-2 pretreatment.

Quite different results were obtained, however, when PECs from BCG-injected or proteose-peptone-injected mice were tested; such injections result in 'activation' of the macrophage population by a variety of criteria<sup>2,5</sup>, and, as shown in Table 1, such activated PEC populations retained a high degree of their Fc rosetting ability after anti-H-2 serum pretreatment. Equally significant, the proportions of phagocytic cells and anti-H-2-resistant Fc rosettes in these cell suspensions were almost equal (Table 1). It thus seems that it is the activated macrophages which are resistant to the inhibiting effects of the anti-H-2 serum. This was verified by testing plastic-adherent (macrophage-rich) compared with non-adherent (lymphocyte-rich) cells from these cell suspensions: as shown in Table 1, the adherent cells were only minimally inhibited, whereas non-adherent cells were quite severely impaired in their ability to form Fc rosettes.

Activated (blast) lymphocytes, either B cells mitogenically transformed with *Escherichia coli* lipopolysaccharide<sup>8</sup> (LPS) or T cells activated to allogeneic antigens *in vivo*,

Fig. 1 Cytotoxicity of CBA anti-DBA/2 (anti-H-2<sup>d</sup>) serum on DBA/2 spleen (a) or peritoneal exudate cells (PEC) from peptone-stimulated mice (b), using GPC or RC as sources of complement. Dead cells were assessed by Trypan blue uptake<sup>20</sup>. The PEC population contained about 65% phagocytic cells before testing. The GPC (●) and RC (○) were both purchased from Gibco in a lyophilised form. The GPC was used at a dilution of 1:6. The RC was first extensively absorbed with mouse RBCs, spleen, thymus and various mouse tumour culture cell lines to remove naturally occurring antibodies against mouse nucleated cells. It was then used at a dilution of 1:2. The cytotoxic curve of anti-H-2<sup>d</sup> serum on normal PECs was very similar to that found with spleen. These experiments were repeated many times using different sources of GPC, including fresh guinea pig serum, and different batches of anti-H-2<sup>d</sup> serum, the same results being obtained.

**Table 1** Effect of anti-H-2 serum preincubation on the ability of various cell populations to form Fc rosettes\*

\*Fc rosettes were assessed using SRBCs coated with a 1/100 (subagglutinating) dilution of a heat-inactivated rabbit hyperimmune anti-SRBC serum, as described previously<sup>12</sup>. Also previously described<sup>12</sup>: the Fc rosette assay, preparation and properties of the anti-H-2<sup>d</sup> (CBA anti-DBA/2) serum, and preparation of the various DBA/2 strain cell suspensions. The inhibitory effect of anti-H-2<sup>d</sup> serum was assessed by preincubating  $0.5 \times 10^6$  cells, previously pelleted by centrifugation with 0.1 ml anti-H-2<sup>d</sup> serum or NMS (normal CBA mouse serum) for 20 min, centrifugation of the cells followed by removal of the serum and addition of 0.5 ml of a 1% suspension of the antibody-coated SRBCs. Rosettes were then made and counted using crystal violet to stain the rosetted cells<sup>12</sup>. Phagocytic cells were assessed by ingestion of latex beads<sup>22</sup> or the osmotic lysis technique<sup>12,23</sup>. The latex method was found to be more reliable when assessing normal macrophages. Selection of adherent and non-adherent PECs was as described previously<sup>12</sup>. The results recorded represent the mean of 4–6 experiments ± standard deviation.

‡B cells were activated in culture by the mitogen *E. coli* LPS<sup>9</sup> as described previously<sup>24</sup> and were collected after 3 d. Such cultures contained about 50% 'blast' cells of which over half were Fc receptor-positive.

†Graft versus host (GvH) spleen refers to spleen cells from lethally irradiated (850 R) C<sub>3</sub>D<sub>2</sub>F<sub>1</sub> mice injected with  $50 \times 10^6$  DBA/2 spleen cells beforehand to obtain activated T cells<sup>19</sup>.

§The P815 line as well as the others are long term established tissue culture cell lines. The P388D<sub>1</sub> cells<sup>10</sup> were provided by Dr H. Koren, National Institutes of Health. The FVL (Friend virus leukaemia) cells were donated by Dr J. C. Kennedy, Queen's University, Department of Pathology. Cells were taken from both stationary and log-phase cultures which account for part of the variability in Fc rosette counts after NMS.

¶DBA/2 mice were injected with  $10^6$  SaD/2 tumour cells, the tumours removed 3–4 weeks later and a single cell suspension made as described previously<sup>12</sup>.

||The SaD/2 tumour cell suspensions were treated with iron filings and magnetism as described previously<sup>12</sup> to remove macrophages. Mean of two experiments recorded.

some of which may be Fc receptor-positive<sup>9</sup>, behaved like their normal counterparts with regard to anti-H-2-mediated inhibition of Fc rosette formation (Table 1).

Thus, activated macrophages, in contrast to normal macrophages, normal lymphocytes and activated lymphocytes are capable of forming Fc rosettes after treatment with relevant anti-H-2 serum. These animal experiments can be mimicked using cells from long term established tissue culture lines which are Fc receptor positive. Whereas cells from the L1210 myeloid leukaemia, a Friend-virus-induced erythroleukaemia, and the P815 mastocytoma were all totally inhibited, the P388D<sub>1</sub> cell line—which is a macrophage-like cell line<sup>10</sup>—retained its full Fc rosetting ability (Table 1).

The possibility of exploiting the observation that activated macrophages can still form Fc rosettes after anti-H-2 treatment as a 'marker' to screen cell suspensions for their presence would seem verified by further experiments (Table 1) in which cell suspensions made from solid fibrosarcoma tumours—which are often known to contain many macrophages<sup>11,12</sup> which can be in an activated state<sup>13</sup>—were tested for the presence of phagocytic cells and anti-H-2 resistant Fc rosette-forming cells. The respective proportions of these cells were very similar, and previous removal of phagocytic cells from the tumour cell suspensions left a residual population of Fc rosette-forming cells which were capable of being totally inhibited by anti-H-2 serum pretreatment.

The reasons why activated macrophages retain their Fc rosetting ability after anti-H-2 treatment are not clear. Some possibilities include: a possible significant drop in the relative density of H-2 antigens on macrophages when they become activated; the number and avidity of Fc receptors are both known to increase on macrophages when they become activated<sup>4,14</sup>; an antigen, other than H-2, to which antibodies in the polyspecific anti-H-2 sera can react, may be present on normal macrophages but not on activated macrophages, thus effectively diluting the potency of the anti-H-2 sera. If this is the case, the Ia

antigens may be involved, as these are present on normal macrophages<sup>15,16</sup> but may not be on activated macrophages<sup>17</sup>.

The first possibility may explain why activated macrophages seem relatively resistant to the cytotoxic effects of anti-H-2 serum and guinea pig complement<sup>12</sup> (GPC). As shown in Fig. 1, killing of such cells requires a much more potent source of complement (in this case rabbit serum<sup>18</sup>) for the cells to be killed. In contrast, normal lymphocytes are easily killed by anti-H-2 serum and GPC, as are activated lymphoid cells<sup>19,21</sup>. These results indicate caution should be exercised when using anti-H-2 sera and GPC as cytotoxic markers on lymphoreticular cell populations as one may inadvertently select for any activated macrophages that may be present.

In summary, it has been found that activation of macrophages is accompanied by an increased resistance of these cells to anti-H-2 serum mediated cytotoxicity and inhibition of Fc (EA) rosette formation; the latter observation can apparently be applied successfully as a simple marker to detect activated macrophages.

I thank Mrs B. Lawson and Miss Man Shan Man for assistance. This work was supported by the National Cancer Institute of Canada.

## H-2-like specificities of foreign haplotypes appearing on a mouse sarcoma after vaccinia virus infection

ATTENTION has focused recently on the interaction of viruses and histocompatibility antigens, and it has been proposed that this relationship may be central to immune surveillance<sup>1-3</sup>. We report here the new expression of H-2 specificities apparently of other haplotypes on the surface of a chemically induced mouse tumour cell line following vaccinia virus infection.

A sarcoma induced by 3-methylcholanthrene (Meth A, H-2<sup>d</sup>) was passaged in syngeneic mice (BALB/c, H-2<sup>d</sup>). At the time of passage, the recipients were also infected intraperitoneally with vaccinia virus. Control BALB/c mice received tumour but no virus. After 7 d tumour cells were taken from the peritoneal cavity from both infected and control mice, washed and tested for a wide range of H-2 antigenic specificities—both public and private. We used a new microradioassay that involves antibody-complement treatment of the target tumour cells followed by testing for the uptake of <sup>14</sup>C-uridine in a postlabelling assay (manuscript in preparation).

We found the normal H-2<sup>d</sup> haplotype specificities in the control tumour (private H-2D.4, H-2K.31 and public H-2 3,8,28, and 35), whereas in the tumour from infected animals we repeatedly and reproducibly found reactions with anti-H-2 sera of restricted specificity apparently detecting ten additional private and three public specificities—normally present only in mice of other H-2 haplotypes (Table 1). The extra-reactivities seemed to be restricted to anti-H-2 sera, since normal mouse sera from various strains, antisera against non-H-2 antigens (Thy 1.2; Ly 4.2) and, interestingly, antisera against I-region-associated (Ia) antigens did not react. The extra specificities were found 5-7 d after infection but after 2 weeks there was no difference between tumour cells from infected and control animals. This time course roughly parallels that of the

**Table 1** Cytotoxic activity of anti H-2 sera against Meth A sarcoma cells grown in syngeneic mice in the absence (control) or presence of vaccinia virus

5 × 10<sup>6</sup> Meth A tumour cells were injected with or without vaccinia virus (10<sup>7</sup> infectious units of Lister strain) into BALB/c mice. 7 d later the tumour cells from both groups were collected from the peritoneum and washed. 2 × 10<sup>4</sup> macrophage-depleted Meth A tumour cells (infected or control) in 50 µl culture medium were incubated in round-bottom wells of sterile microtitre plates with 1 µl of antiserum for 1 h at 4 °C and then 30 min with 50 µl of prediluted (1/10) rabbit complement at room temperature (C°). 10 µl <sup>14</sup>C-uridine (0.3 µCi ml<sup>-1</sup>; 402 mCi mmol<sup>-1</sup>) were added to the plates for a further 16 h. The cultures were collected in a semiautomatic machine. The results are expressed as the percentage reduction in uridine uptake in test samples compared with control samples with complement and no antibody. Similar results were obtained by measuring <sup>14</sup>C-thymidine uptake. The results were also reproduced in a conventional microcytotoxicity titration using serially diluted antisera.

\*The anti-H-2 sera represent sera of the D series raised under contract by the Transplantation Immunology Branch of the National Institutes of Health. For details see National Institutes of Health catalogue and supplements<sup>23</sup>, anti H-2D.12 and anti H-2.11 reacted weakly with normal Meth A tumour cells and not with H-2<sup>d</sup> lymphocytes. Anti H-2K.15, H-2K.17 and H-2.18 seem to contain an unidentified antibody which reacted weakly with H-2<sup>d</sup> lymphocytes. Anti H-2.16 also contains anti 34 which could explain the cytotoxicity against Meth A control. A TH anti-A.TL was obtained from Dr Chella David, the other sera were raised in the London Hospital Medical College.

†Private specificities present on H-2<sup>d</sup> lymphocytes: H-2D.4, H-2K.31; public: H-2.3, 8, 13, 28, 35 (ref. 22).

\*100 µl of 1/10 diluted antiserum was absorbed with 10<sup>8</sup> spleen cells from B10, B10.BR or B10.A mice for 1 h at 4 °C and tested in presence of complement for cytotoxic activity against normal Meth A, Meth A from vaccinia-infected mice (day 7) and Gardener lymphoma. The tumour cells were then postlabelled by culturing them overnight with <sup>14</sup>C-uridine

†<sup>14</sup>C-uridine uptake in the controls (treated with complement alone) was for Meth A 3.114 ± 251, for Meth A + vaccinia 2.296 ± 132 and for Gardener lymphoma 2.316 ± 613.

induction of cytotoxic T cells against vaccinia-infected syngeneic target cells<sup>4</sup>.

The results in Table 2 show that the extra-reactivity with anti-H-2D.32, directed against a private specificity of the H-2<sup>k</sup> haplotype, could be absorbed with spleen cells from B10.BR (H-2<sup>k</sup>, D32 positive) but not from B10.A (H-2<sup>a</sup>, D.32 negative) mice. Furthermore, cytotoxic activity of anti-H-2.1 could be absorbed with cells from B10.A (positive for 1, a public specificity) but not from C57BL/10 (B10, negative for 1). But we also had experiments in which there was nonspecific removal of activity by normal lymphoid cells. It is unlikely that the extra-reactivities are due to anti-virus activity in the sera because anti-virus activity could not be removed by such a procedure<sup>5,6</sup>.

In theory new antigenic expression can be due to: (1) direct alteration of the H-2 specificities on the cell surface as suggested by Doherty and Zinkernagel<sup>7</sup>; (2) introduction of new surface determinants coded for or induced by the virus genome; these determinants could cross react with and have similar properties as histocompatibility antigens<sup>7,8</sup>; (3) derepression of pre-existing genetic information for H-2 specificities of different haplotypes (see discussion by Martin<sup>9</sup> and Bodmer<sup>10</sup>).

We have no evidence for alteration of the normal H-2 specificities on the Meth A tumour cell since the cells from infected mice could absorb anti-H-2 antibody directed against the private specificities of the syngeneic strain (H-2D.4 and H-2K.31). The next possibility of direct viral action modifying the 'H-2 profile' or creating new 'H-2 like' determinants is an attractive one which we can neither prove nor disprove. An even more attractive possibility, for which we also have no proof, is derepression. Derepression could explain findings in the TL system in mice<sup>11</sup> and the Gm allotype system in man<sup>12</sup>, indicating that allelic differences may be the products of closely linked genes and the genetic polymorphism is exerted on the level of the control of whichever of the genes may become expressed<sup>10</sup>. With regard to our findings, it could be anticipated that the polymorphism breaks down when the virus interferes with the metabolism of the tumour cell.

It is not known whether other H-2-associated polymorphisms, like for instance lymphocyte-activating determinants (LADs) are also affected in this manner but some findings point in this direction: (1) leukaemic cells were able to stimulate syngeneic remission lymphocytes<sup>13,14</sup>; (2) during virus infection there was a transient stimulation in the mixed lymphocyte reaction between HLA identical lymphocytes (J. R. Salaman and H. Festenstein, unpublished); (3) influenza virus-infected lymphocytes stimulated syngeneic lymphocytes<sup>15</sup>; (4) the abnormally high stimulation of normal lymphocytes by human cell lines,

most likely infected with Epstein-Barr virus<sup>16</sup>. In this context particularly, it is interesting that we could not detect the emergence of Ia antigens on the infected tumour cells (Table 1).

Many questions are raised by these findings, particularly concerning the basis of surveillance against infections and tumours. The findings also highlight the role of the various components of the major histocompatibility system in alloimmune interactions<sup>17</sup>. If some tumours were to express one kind of H-2-like determinant rather than another, would this enable a tumour to grow better in some instances and less well in others, as recent reports<sup>8,18</sup> suggest? We have preliminary data indicating a suppressive effect of vaccinia virus on tumour growth and there is a recent report on a similar effect of vaccinia virus on human melanomas<sup>19</sup>. Relevant also in this context are experiments showing syngeneic graft rejection after infection by lymphomagenic virus<sup>20</sup>. Derepression of H-2 and possibly non-H-2 transplantation systems could be a normal surveillance mechanism analogous to the somewhat artificial situation of an alloimmune interaction. It also raises the question whether changes in immunogenicity induced chemically<sup>21</sup> or by irradiation (paper presented by J. McBurney and T. R. Munro, Second European Immunology Meeting, Amsterdam, 1975) could have similar mechanisms.

Our observations may point to the possibility of inducing rejection in one situation (tumours) and to provoking loss of immunogenicity in others (transplants). If this can be done, we may approach an understanding of "the pre-occupation of the immune system with histocompatibility antigens"<sup>1</sup> and the surveillance of transplants and tumours.

We thank the National Institutes of Health for H-2 alloantisera and S. G. Nathenson and P. Demant for helpful discussion. We thank Professor Osorio (Department of Physiology, University of Granada, Spain) and the Cancer Research Campaign for financial support.

## Surface membrane alterations in somatic cell hybrids of neuroblastoma and glioma cells

SOMATIC cell hybrids have been used to discern many properties of parental cells. Genes for neuronal properties can be activated in hybrids formed by fusion of mouse neuroblastoma and rat glioma cells (refs 1 and 2, and B. Hamprecht, T. Amano and M. Nirenberg, personal communication). These cell hybrids resemble the parent neuroblastoma cells in many of their properties as they can be induced to extend long neurites and possess electrically excitable membranes<sup>1</sup>. In addition the cell hybrids express other neuronal characteristics that are less pronounced in the parental cells, such as choline acetyltransferase<sup>1</sup>, and morphine receptors<sup>2</sup>. Many of the above properties suggest alterations in the surface membrane. We have shown previously that a particular group of glycopeptides is more prominently expressed on the cell surface in clones of mouse neuroblastoma which have the ability to undergo morphological differentiation than in clones that are unable to extend neurites<sup>3</sup>. In the present report, we show that this group of glycopeptides is abundant in the surface membranes of the hybrid cells.

The parent cell lines were: N18TG-2, a mouse neuroblastoma clonal line resistant to 6-thioguanine<sup>4</sup> and C6BU-1, a 5-bromodeoxyuridine-resistant clone of rat glioma<sup>1</sup>.

**Fig. 1** Chromatography on Sephadex G-50 of Pronase-digested trypsinates from mouse neuroblastoma clone N18TG-2 and hybrid NG108-15 cells grown in the presence of L-<sup>14</sup>C- or <sup>3</sup>H-fucose, respectively. Trypsinates were combined, digested with Pronase and chromatographed as described<sup>3</sup>. Sephadex G-50 profile of Trypsinate A (loosely-associated glycopeptides) (a) and Trypsinate B (tightly-associated glycopeptides) (b) from N18TG-2 (○) and NG108-15 (●) cells. BD represents fractions in which Blue Dextran 2000 was eluted. Phenol red eluted at fraction 105.

**Fig. 2** Chromatography on Sephadex G-50 of Pronase-digested trypsinates from mouse neuroblastoma N18TG-2 and hybrid NG108-5 cells grown in the presence of L-<sup>14</sup>C- or <sup>3</sup>H-fucose, respectively. Trypsinate A (a) and Trypsinate B (b) from N18TG-2 (○) and NG108-5 (●) cells. Details are described in Fig. 1.

Hybrids of these parental lines, NG108-5 and NG108-15 were obtained by Sendai virus-induced fusion of the neuroblastoma and glioma clones (B. Hamprecht, T. Amano and M. Nirenberg, personal communication). All these cells were obtained from Dr M. Nirenberg, NIH. The modal chromosome numbers for C6-B4-1 and N18TG-2 are 39 and 83 respectively, whereas the hybrids have chromosome numbers higher than the sum of the parental cells. These and other characteristics of the hybrids have been reported<sup>5,6</sup>. The cells were grown to confluency in Dulbecco's modified Eagle's medium (DMEM) with 10% foetal calf serum, at which time the glycoproteins were made radioactive by incubating the cells for 2 d in medium containing L-<sup>3</sup>H- or <sup>14</sup>C-fucose (4.8 Ci mmol<sup>-1</sup> and 57 mCi mmol<sup>-1</sup>, respectively, Amersham). These procedures as well as those for collecting cells have been described<sup>3</sup>. The membrane glycopeptides were removed from the cell surface by sequential trypsinisation since different groups of glycopeptides are distinguished by this procedure<sup>3</sup>. One group is preferentially removed by the first trypsinisation step (Trypsinate A) suggesting that these glycopeptides are more accessible or loosely associated with the membrane<sup>7</sup>. Trypsinate B, which is removed with the second trypsin treatment, contains the more tightly-associated glycopeptides. All radioactive trypsinates to be compared were combined, digested exhaustively with Pronase (Calbiochem) and chromatographed on a column of Sephadex G-50 (ref. 3). Choline acetyltransferase (CAT) and acetylcholinesterase (AChE) were assayed according to Blume *et al.*<sup>8</sup>. Duplicate extracts at two concentrations of cells in the confluent state were used. The formation of acetylcholine by CAT was verified using electric eel AChE<sup>9</sup>. Specific AChE was determined by including 10<sup>-5</sup> M BW-284C51 dibromide (Wellcome) in the assay mixture.

The chromatographic profiles of the loosely-associated glycopeptides (Trypsinate A) from the surface of the parent neuroblastoma and hybrid cells were found to be similar (Figs 1a and 2a), and slightly different from that of the parent glioma cells (Fig. 3a). On the other hand, the pattern of the more tightly-associated glycopeptides

**Table 1** L-<sup>3</sup>H-fucose incorporation into parental and hybrid cells

Clonal lines	L- <sup>3</sup> H-fucose incorporation		Trypsinate	
	c.p.m. per 10 <sup>6</sup> cells	c.p.m. per µg protein	A	B
Parents				
Mouse neuroblastoma				
N18TG-2	2,150	63	4	3
Rat glioma C6BU-1	235	15	8	4
Hybrids				
NG108-5	13,134	154	7	2
NG108-15	4,235	74	7	4

Confluent cultures, in 60-mm dishes, were incubated in 7 ml medium containing L-<sup>3</sup>H-fucose for an additional 51 h (477,500 c.p.m. per ml medium). Cells were washed four times with cold 0.16 M NaCl and removed from the monolayer with 1 ml 0.25% trypsin solution (3 min at room temperature). To the cell suspension, 1 ml medium containing 10% foetal calf serum was added and aliquots removed for radioactive counting. Values for the trypsinates were obtained from another set of radioactively labelled cultures. Sequential trypsinisation was carried out as described previously<sup>3</sup>.

(Trypsinate B) from the parent neuroblastoma cells differed markedly from those of the hybrid and glioma cells (Figs 1b, 2b and 3b). The chromatographic profiles of the tightly-associated glycopeptides from the parent neuroblastoma cells may be divided into early eluting groups (Fig. 1b, fractions 15–30), more slowly eluting groups (Fig. 1b, fractions 31–50) and dialysable material (fractions 65–80). The latter includes free fucose, and the significance of this material requires further investigation. The early eluting glycopeptides were missing from the material derived from the surface of the hybrid cells (Fig. 1b and 2b) and the parent glioma cells (Fig. 3b). In contrast, the more slowly eluting glycopeptides (fractions 31–50) were similar in all of the cell lines examined. This latter group (fractions 31–50) was also prominent in the neuroblastoma clones which are capable of morphological differentiation and less pronounced in the surface glycopeptides from axon-minus cells<sup>3</sup> or these cells in logarithmic phase of growth (M.C.G., Y.K. and U.Z.L., unpublished).

**Fig. 3** Chromatography on Sephadex G-50 of Pronase-digested trypsinates from mouse neuroblastoma N18TG-2 and rat glioma C6BU-1 cells grown in the presence of L-<sup>14</sup>C- or <sup>3</sup>H-fucose, respectively. Trypsinate A (a) and Trypsinate B (b) from N18TG-2 (○) and C6BU-1 (●) cells. See Fig. 1.

In accordance with previous results (B. Hamprecht, T. Amano and M. Nirenberg, personal communication), high levels of CAT were found in the hybrid cell lines, whereas the activity of this enzyme in both parent cells was low (143,160, 58 and 3.8 pmol per mg protein per min for NG108-5, NG108-15, N18TG-2 and C6BU-1, respectively). The expression of this enzyme was also reported to be activated in a hybrid clone of mouse neuroblastoma NA and human fibroblasts<sup>10</sup>. In addition, AChE activity was expressed in the two hybrids and the parent neuroblastoma cells (14,700, 7,480 and 7,980 pmol per mg protein per min). The parent glioma cells had less activity (82 pmol per mg protein per min).

Less radioactive L-fucose was incorporated into the glioma cells than into either the hybrid or neuroblastoma cells, either expressed as per cell or per mg cell protein. The latter takes into account the size difference of the cell lines (Table 1). Since the percentages of the total incorporated fucose which were removed by the trypsinisations were similar, the fucose-containing glycoproteins may be deficient in the membranes of the glioma cells. The cells were grown in the presence of radioactive fucose for 51 h, so the amounts probably do not reflect increased turnover of the membrane glycoproteins. These results suggest that in this phenotypic expression of the fucose-containing glycoproteins the traits more characteristic of the neuroblastoma cells continue to be preserved or even activated in the hybrids. Closer scrutiny of the fucose-containing glycopeptides using chromatographic profiles (Figs 1b and 2b), however, showed only a partial preservation in the hybrids of the phenotypic expression of the neuroblastoma cells. More detailed analyses of the glycoproteins will be required to determine if the glioma phenotype is preserved at all.

The hybrid cell lines were shown to undergo biochemical, morphological and electrical differentiation (B. Hamprecht, T. Amano and M. Nirenberg, personal communication). For this reason, we anticipate that analysis of the membrane glycopeptides from a variety of hybrids will reveal which glycopeptides are associated with the acquisition of these properties. We conclude from the present studies that the glycopeptides which elute early from the Sephadex G-50 column may not be connected with the phenotypic expression of the differentiated state in neuroblastoma cells, since they are missing from the surface of the hybrid cells. It follows that the slowly eluting group of glycopeptides may be associated with the ability to neuroblastoma cells to differentiate. This group consists of several glycopeptides<sup>7</sup>. Since the glioma cells also show a corresponding group of slowly eluting glycopeptides it may be possible with further chemical studies to distinguish between those which the cells may have in common and those which correlate with differentiation. The fact that hybrid cells do not possess the early eluting glycopeptides substantiates our earlier finding<sup>3</sup> that the slowly eluting glycopeptides are characteristic of the differentiated state of neuroblastoma cells.

We thank Dr M. Nirenberg, NIH, for cell lines and Mrs Danielle Sava for assistance. This work was supported in part by the US-Israel Binational Science Foundation, the American Cancer Society and the Public Health Service.

## Tumour promotor induces plasminogen activator

INFECTION of chick embryo fibroblasts with Rous sarcoma virus (RSV) induces a cell-specified plasminogen activator<sup>1</sup>. Induction occurs with transforming viruses but not with lytic viruses or with oncornaviruses which are not themselves transforming<sup>2</sup>. Similarly, many mammalian cell lines and embryo cultures transformed with either viruses or chemical carcinogens may be high producers of plasminogen activator in contrast to their untransformed counterparts<sup>3-6</sup>. A correlation has been demonstrated between production of plasminogen activator and various features of the transformed phenotype, such as cell locomotion, morphology and loss of anchorage-dependent growth<sup>4,7</sup>. Several established cell lines which are not highly tumorigenic or transformed by the usual criteria are, however, active producers of plasminogen activator; there are examples also of transformed or tumorigenic cell lines which do not produce significant levels of plasminogen activator<sup>3,8-10</sup>.

We have been interested in the regulation of the expression of plasminogen activator in the expectation that an understanding of the mechanism of its control and an ability to alter its levels with exogenous agents would provide insights into its physiological significance in the

**Fig. 1** A dose study of PMA in CEF cells. Subconfluent plates of CEF (approximately  $5 \times 10^6$  cells per 9-cm dish) were re-fed growth medium containing PMA at the indicated concentrations. After 24 h cells were washed twice with phosphate-buffered saline and collected by scraping into 2 ml of swelling buffer (10 mM Tris, 10 mM NaCl, pH 8.0) without detergents. Lysates were diluted 1:10 into assay buffer (100 mM Tris, 10 mM NaCl, 3 mM  $\text{NaN}_3$ , pH 8.0) and assayed in triplicate as described by Unkeless *et al.*<sup>1</sup> on fibrin-coated plates containing 40,000-70,000 c.p.m. of  $^{125}\text{I}$ -fibrin ( $10 \mu\text{g cm}^{-2}$ ) in the presence of 4  $\mu\text{g per ml}$  human plasminogen previously purified by lysine-Sepharose affinity chromatography<sup>13</sup>. Aliquots were taken after 3 h and the solubilised fibrin determined by scintillation counting (Nuclear Chicago) in Aquasol (New England Nuclear Corp.) using the  $^3\text{H}$  channel. Percentage fibrin digested was determined from the ratio of the counts released in the presence of sample (adjusted for fibrin released in the presence of plasminogen but in the absence of sample) to the total counts released by trypsin.

**Fig. 2** Time course of induction. *a*, Cell lysate assay. Agents were added to replicate subconfluent plates of CEF at zero time and at the subsequent times indicated in the figure cells were collected and lysates assayed as described in Fig. 1.  $\Delta$ , Untreated CEF;  $\circ$ , CEF treated with  $5 \times 10^{-8}$  M PMA;  $\square$ , CEF treated with  $5 \times 10^{-8}$  M PMA and  $1 \mu\text{g ml}^{-1}$  actinomycin D. *b*, Intact cell assay. Assays were carried out according to Unkeless *et al.*<sup>2</sup>. CEF ( $2 \times 10^6$ ) were plated in triplicate on to 6-cm plates coated with 50,000 c.p.m.  $^{125}\text{I}$ -fibrin ( $10 \mu\text{g cm}^{-2}$ ). The medium was Dulbecco's with 10% foetal calf serum. Six hours after plating (zero time), various agents were added to the plates. Aliquots were taken at the times indicated in the figure and percentage fibrin digested determined as described in the cell lysate experiments.  $\bullet$ , Untreated CEF;  $\square$ , CEF treated with  $1.5 \times 10^{-8}$  M PMA;  $\circ$ , CEF treated with  $1.5 \times 10^{-8}$  M PMA and  $10^{-6}$  M phorbol;  $\blacksquare$ , CEF treated with  $10^{-6}$  M phorbol;  $\Delta$ , CEF treated with  $5 \times 10^{-8}$  M PMA.

normal and malignant state. We reported that glucocorticoids inhibit expression of plasminogen activator in certain cell lines<sup>10</sup>. Troll *et al.* found that a phorbol ester, phorbol-12-myristate-13-acetate (PMA), a component of croton oil which causes epidermal inflammation, hyperplasia and tumour promotion in treated skin<sup>11</sup>, also induces increased trypsin-like proteolytic activity in treated mouse skin<sup>12</sup>. In view of these findings, we tested the effects of PMA on plasminogen activator levels in cultured cells, and report here that PMA is a potent inducer of plasminogen activator in chick embryo fibroblasts and HeLa cells.

Plasminogen activator was assayed by published methods<sup>1,2</sup> (see legends to Figs and Table for details). The assay is based on quantification of the solubilisation of  $^{125}\text{I}$ -labelled fibrin due to proteolytic digestion in the presence of plasminogen and sample. The sample may be either intact cells, plated directly on to a fibrin-coated dish, or a lysate of cells. In our studies, omission of plasminogen from the assay of PMA-induced cells or cell lysates reduced fibrinolysis by more than 95%, indicating that the fibrinolysis was plasminogen dependent. This justifies our referring throughout to the induction of a plasminogen activator.

**Table 1** Maximum-fold increase in cell-associated plasminogen activator over endogenous levels after exposure to PMA

Cell	Origin	Time in culture	Maximum-fold increase in plasminogen activator
CEF	Chick embryo fibroblast	1-3 weeks	10
HeLa <sup>20</sup>	Human cervical carcinoma	20 yr	10
HEC	Hamster embryo cells	1-3 weeks	3
REC	Rat embryo cells	1-3 weeks	2
HTC <sup>21</sup>	Rat hepatoma	10 yr	2
L <sup>20</sup>	Mouse fibroblast	20 yr	1

Exposure was for 24 h and ranged from 10 to 1,000 ng ml<sup>-1</sup>. Cells were grown as monolayer cultures in either Dulbecco's modified Eagle's minimal essential medium (DMEM) with 5% foetal calf serum (FCS) (L cells), DMEM+10% FCS (CEF, HEC, REC, HeLa) or Ham's F12 Medium + 10% FCS (HTC). Embryo cultures were prepared by standard procedures<sup>22,23</sup> from 9-12-d chick embryos, midterm pregnant rats or late term pregnant hamsters. Cell lysates were prepared and assayed as described in the legend to Fig. 1.

The dose-response curve of chick embryo fibroblasts (CEF) to PMA is shown in Fig. 1. Induction occurred at a concentration as low as  $5 \times 10^{-9}$  M PMA ( $3 \text{ ng ml}^{-1}$ ). Maximal induction was observed at  $1.5 \times 10^{-8}$  M. The time course of induction of plasminogen activator in CEF as assayed in cell lysates and intact cells is shown in Fig. 2a and b. Increased fibrinolytic activity in lysates (cell-associated plasminogen activator) was observed as early as 3 h after exposure to PMA (Fig. 2a). The longer delay in the appearance of extracellular fibrinolytic activity assayed with intact cells (Fig. 2b) reflects the lower sensitivity of this assay, since in Fig. 2b foetal calf serum was used as a source of plasminogen. When intact cells were assayed using foetal calf plasminogen, purified by lysine-Sepharose affinity chromatography<sup>13</sup>, rather than serum, induction was detected after 3 h (data not shown). Phorbol itself, which is inactive as a tumour-promoting agent<sup>11</sup>, neither induced nor blocked induction (Fig. 2b). Actinomycin D completely blocked the response to PMA (Fig. 2a), suggesting that PMA induction requires RNA synthesis.

The induced levels of plasminogen activator gradually returned to control values within 12 h of removal of PMA. Curiously, the deinduction was also blocked by actinomycin D. In this regard, deinduction resembles the glucocorticoid-induced repression of plasminogen activator expression in rat hepatoma cells, which is also blocked by actinomycin D (ref. 10).

PMA is not toxic to early passage CEF at  $5 \times 10^{-8}$  M as judged by growth rate during a 4-d exposure; however, it did inhibit growth of late (eighth) passage CEF. A growth inhibitory effect of PMA on late passage CEF has also been reported by Diamond *et al.*<sup>14</sup>. In spite of the different effects on growth at early and late passage, the kinetics of induction of plasminogen activator were found to be the same at both passage times.

Several cell types were screened for response to PMA (Table 1). PMA produced approximately a tenfold elevation of plasminogen activator in HeLa and CEF. A two- to threefold increase was seen with hamster embryo cells, rat embryo cells and a rat hepatoma cell line, and no induction was found with the mouse L cell line. Unresponsive cell types may prove useful in an analysis of the mechanism of the PMA response.

Phorbol esters, in addition to causing epidermal hyperplasia, inflammation and tumour promotion, have various other biological effects. These include alterations in cell morphology, growth properties and increased <sup>3</sup>H-choline incorporation in cultured cells<sup>14-16</sup>; mitogenesis in mouse 3T3 cells and lymphocytes<sup>17</sup>; a rapid but short lived increase in cyclic GMP in lymphocytes and mouse 3T3 cells<sup>17</sup>; decreased cyclic AMP levels in mouse skin<sup>18</sup>; and enhancement of cell transformation by chemical carcinogens in cell culture<sup>19</sup>. Our discovery that extremely low concentrations of PMA induce a marked increase in plasminogen activator in such diverse systems as CEF and

HeLa cells, together with the previously described *in vitro* effects of this compound, suggest that PMA induces a constellation of changes reminiscent of the phenotype of cells transformed by oncogenic viruses or chemical carcinogens, a major difference being that the effects of PMA are readily reversed when the agent is removed. An analysis of the mechanism of action of PMA in cell culture may, therefore, shed light on the general problem of malignant transformation.

We thank Dr Sidney Belman for phorbol compounds and helpful discussions. This research was supported by a contract and a research grant from the National Institutes of Health.

## Evidence for inhibition of platelet activation in blood by a drug effect on erythrocytes

ADP released from erythrocytes causes adhesion and aggregation of platelets<sup>1</sup>. This can presumably happen *in vivo*

when circulating red cells undergo haemolysis in pathological conditions<sup>2,3</sup>, even though ADP is hydrolysed by enzymes present in blood<sup>4-7</sup>. More important pathologically, as a factor in thrombogenesis, is the possibility that ADP is also released from red cells which are structurally and metabolically normal. ADP might leak from circulating cells undergoing reversible deformations<sup>8</sup> which are much increased by abnormal conditions of flow, for example in vessels narrowed by atherosclerosis.

Experimentally, the adhesiveness of platelets to glass is increased by the presence of erythrocytes without evidence of haemolysis; and the increase is abolished by apyrase which catalyses the dephosphorylation of ADP<sup>9</sup>. When heparinised blood from anaesthetised pigs is made to flow through extra-corporeal shunts, deposits of platelets form at branch points but nowhere else<sup>10</sup>; and no deposits form with platelet-rich plasma, indicating that haemodynamic effects on red cells suffice to increase platelet adhesiveness.

The resistance of erythrocytes to hypotonic haemolysis is increased by low concentrations of various drugs, including chlorpromazine and other phenothiazines<sup>11</sup>. The mechanism by which these substances increase the resistance of red cells may alter their membrane so as to diminish or prevent the leakage of ADP; and if so, such an effect should show itself as a diminution of the reactivity of platelets in flowing blood. We have therefore determined the effect of chlorpromazine on the 'bleeding time' from a small hole in an artificial vessel, the extravasation being terminated, as *in vivo*, by a plug of platelets. The proposition that any diminution in platelet reactivity resulted from an effect of chlorpromazine on the red cells required that the bleeding time was prolonged by concentrations below those at which the drug inhibits the release reaction of platelets<sup>12</sup>.

Human blood was obtained from the antecubital veins of apparently healthy volunteers who had not taken aspirin or any similar drug in the preceding week. The blood was mixed with trisodium citrate (final concentration 0.38%) as anticoagulant. The concentration of platelets varied from  $1.36 \times 10^8$  to  $2.40 \times 10^8$  ml<sup>-1</sup>. Blood was centrifuged at 280g for 15 min for preparing plasma containing  $2.40 \times 10^8$ – $3.82 \times 10^8$  platelets ml<sup>-1</sup>.

For each experiment, whole blood or platelet-rich plasma was pumped continuously from a reservoir through polyethylene tubing about 30 cm long and 0.3 mm internal diameter; the flow rate was 0.16 ml min<sup>-1</sup>. The tube crossed a glass plate under a microscope (Leitz Laborlux) where it was continuously bathed in a stream of Tyrode's solution at 37.5 °C. A small cut was made through about one-third of the circumference of the tube and the duration of 'bleeding' into the bathing solution

was determined up to a maximum time of 600 s. Results are presented as median as well as mean ( $\pm$ s.e.m.) bleeding times in Table 1.

For blood alone the median bleeding time was 130 s and for platelet-rich plasma 600 s. Thus, although the concentration of platelets was always higher in plasma than in blood, the bleeding time was much shorter with blood than with plasma; presumably the difference was due to some influences of the red cells.

Chlorpromazine (Hibernal; Leo AB Halsingborg, Sweden) was added to blood in the reservoir and the median bleeding time was more than doubled by the drug at  $1.6 \times 10^{-6}$  M, which is about 30 times less than the concentration required for halving the release reaction *in vitro*. Higher concentrations increased the bleeding time further, so that the 10-min limit was reached with about  $1 \times 10^{-5}$  M chlorpromazine.

$\beta$ -Diethylaminoethyl-diphenylpropylacetate (Proadifen; SKF 525A, Smith, Kline and French Ltd, Welwyn Garden City, England) also increases the resistance of erythrocyte membranes<sup>13</sup> and at  $1 \times 10^{-6}$  M increased the median bleeding time almost threefold.

The median bleeding time was also prolonged increasingly by the enzyme apyrase (Sigma) in concentrations of 0.5–50  $\mu$ g ml<sup>-1</sup>; but less at 500  $\mu$ g ml<sup>-1</sup>, possibly because of a nonspecific effect of so much added protein. The increase in bleeding time caused by apyrase is most simply accounted for by an accelerated breakdown of free ADP, preventing its activating effect on platelets.

The observations are compatible with our proposition that a drug such as chlorpromazine, which increases the resistance of red cells, can decrease the leakage of ADP from them in conditions in which this shows itself as a diminution in the activation of platelets in the blood. The hypothesis is thus that the activation of platelets by red cells depends on a chemical mechanism produced by released ADP. In flowing blood, red cells also affect platelets through a physical mechanism, by increasing the diffusivity of platelets by up to two orders of magnitude (see ref. 14). Presumably this greatly increases the frequency with which circulating platelets collide with vessel walls and such a physical effect is, indeed, required to account for the rate at which platelet thrombi are observed to grow when produced experimentally in living blood vessels<sup>15-17</sup>. The absence of platelet aggregation in plasma which is stirred at high rates<sup>18</sup>, however, indicates that the collisions on which the adherence of platelets to vessel wall and to each other depend do not by themselves make the platelets adhesive. That depends on their chemical activation by ADP.

**Table 1** Effect of chlorpromazine, SKF 525A or apyrase on the median and mean bleeding times from a small cut in polythene tubes (for method see text)

		see text					
	Addition	Concentration	Number of determinations	Bleeding time (s)		Bleeding time greater than 10 min (%)	
				Median	Mean ( $\pm$ s.e.m.)		
Blood	None (Controls)		70	130	208	19.7	7
	Chlorpromazine	(M)					
		$1.6 \times 10^{-6}$	15	280	271	40.3	7
		$3.2 \times 10^{-6}$	15	390	396	53.3	40
		$8.0 \times 10^{-6}$	15	560	437	47.3	40
		$1.6 \times 10^{-5}$	15	600	(509)	41.4)	73
	SKF 525A	$1.0 \times 10^{-6}$	10	300	340	64.4	10
		$1.0 \times 10^{-5}$	10	540	400	70.4	40
		$1.0 \times 10^{-4}$	11	600	(551)	31.6)	82
	Apyrase	( $\mu$ g ml <sup>-1</sup> )					
		0.5	10	360	349	74.3	40
		5.0	15	430	390	48.3	33
		50	14	600	(546)	29.8)	57
		500	15	170	277	58.6	27
Platelet-rich plasma	None		28	600			96

Other possible explanations of our observations have to be considered. In altering the deformability of erythrocytes<sup>19</sup>, chlorpromazine might affect their flow properties such as to diminish the probability of platelet collisions. Any such effect is unlikely to make a measureable difference in our experiments; nor does it overcome the requirement that the platelets have to be activated before aggregating as an haemostatic plug. Another possibility is that chlorpromazine interferes with the aggregation of platelets after their activation by ADP, for example by competing with calcium<sup>20</sup> which is essential for aggregation. If this were the explanation, however, primary aggregation by added ADP should be inhibited by chlorpromazine in platelet-rich plasma, and this is not so<sup>12</sup>. Furthermore, the concentrations of chlorpromazine which prolong the bleeding time are much lower than the calcium concentration required for platelet aggregation, even in the presence of citrate as anticoagulant.

Direct flow-mechanical activation of platelets has been demonstrated experimentally but in very different conditions<sup>21</sup>. Haemodynamic disturbances produce platelet thrombi in the blood channels of artificial organs such as kidneys or oxygenators, whereby their function is often terminated prematurely<sup>22</sup>. The conclusion that the red cells are primarily responsible for these thrombi accords with the fact that thrombus formation is similar in channels made of various materials as long as the geometry is the same. Our results, therefore, suggest a new way of prolonging the function of such artificial organs through the addition of an agent capable of inhibiting the release of ADP (and ATP) from erythrocytes. Such an agent should, of course, have as few other effects as possible, so that chlorpromazine, although effective, would not be the choice.

Our observations similarly suggest a new approach to the prophylaxis of those thrombotic diseases in which thrombus formation depends on platelets, as in a proportion of acute coronary thromboses. This approach would require the demonstration that the incidence of such a disease is diminished by drugs which, in clinically acceptable blood concentrations, do not inhibit platelet function directly and which inhibit the release of ADP experimentally from non-haemolysing erythrocytes during rheological stress. Our hypothesis may also explain the effect of dipyridamole and sulphapyrazone in preventing increased utilisation of circulating platelets in potentially thrombogenic conditions<sup>23</sup>. This cannot easily be accounted for by any direct action on platelets by either drug at its clinically effective concentration; instead, these drugs may act on the red cells to diminish their activation of platelets.

## Inhibition of plasmin-mediated fibrinolysis by vitamin E

BIOLOGICAL effects attributed to vitamin E include the maintenance of cell membrane integrity, inhibition of enzyme-dependent lipid peroxidation, participation in oxidative phosphorylation, and a general, non-enzymatic antioxidant effect<sup>1</sup>. In spite of these observations, the physiological function of the vitamin remains obscure. Natural deficiency in man has been invoked in the pathogenesis of several disorders, with convincing evidence limited to a specific type of haemolytic anaemia<sup>2</sup>. Therapeutically, vitamin E has its advocates in treatment of peripheral vascular and thromboembolic disease, although documentation for its efficacy is meagre<sup>3</sup>. Although it is considered non-toxic<sup>4</sup>, little is known about adverse effects of excessive dietary vitamin E.

Plasminogen is the plasma proenzyme which, on conversion to its active form, plasmin, is considered responsible for lysis of fibrin deposits resulting from physiological or pathological activation of the coagulation cascade<sup>5</sup>. In spite of interest in vitamin E as therapy for vascular disease, and the importance of coagulation and fibrinolysis in intravascular homeostasis<sup>6</sup>, information on its effects on these processes is limited. An anti-thrombin effect has been claimed<sup>6</sup>, but not confirmed<sup>7</sup>. Prolongation of plasma clotting time has been reported with vitamin E therapy, together with decrease in the expected increment in blood fibrinolytic activity which follows venous occlusion<sup>7</sup>. We report a direct effect of vitamin E on the fibrinolytic system, namely, *in vitro* inhibition of plasmin-mediated fibrinolysis at physiological concentrations of the vitamin and enzyme.

Fibrinolysis was assayed by a sensitive solid phase <sup>125</sup>I-fibrin tube method. This technique, described in detail elsewhere<sup>8</sup>, is based on release of radioactive degradation products from <sup>125</sup>I-fibrin (human), originally absorbed to polystyrene tubes as fibrinogen, and converted to non-cross linked fibrin by thrombin. Plasminogen was isolated from normal human plasma by affinity chromatography on lysine-Sepharose<sup>9</sup>, and subsequent stepwise<sup>9</sup> or gradient elution<sup>10</sup> with ε-aminocaproic acid (EACA). Plasmin was

**Table 1** Effect of vitamin E on lysis of <sup>125</sup>I-fibrin by plasmin and other proteolytic enzymes

	<sup>125</sup> I-fibrin lysed (c.p.m.)		
	- Vitamin E	+ Vitamin E	Δ
Plasmin	9,968	1,634	-84%
Collagenase (Clostridiopeptidase A, Worthington)	18,941	17,870	-6%
Chymotrypsin (α-chymotrypsin, bovine pancreas, Worthington)	36,070	39,539	+10%
Trypsin (bovine pancreas, Worthington)	38,380	44,363	+16%
Pronase (bacterial protease, type VI, Sigma)	51,001	67,864	+33%

Enzyme (5 μg ml<sup>-1</sup>) and vitamin E (1.7 × 10<sup>-5</sup> M) were incubated in <sup>125</sup>I-fibrin coated assay tubes for 30 min at 37 °C (final volume, 0.2 ml in Tris-NaCl buffer). Results are means of duplicate assays. Assay tubes contained 145,000 c.p.m. of <sup>125</sup>I-fibrin (90,000 c.p.m. per μg fibrin).

**Fig. 1** Effect of vitamin E on lysis of <sup>125</sup>I-fibrin by human plasmin. Plasmin, at varying concentrations, was incubated with or without vitamin E ( $0.6 \times 10^{-5}$  M) at  $37^\circ\text{C}$  for 30 min (final volume, 0.2 ml) in assay tubes coated with <sup>125</sup>I-fibrin (140,000 c.p.m. per tube, 90,000 c.p.m. per μg fibrin). Lysis in presence of vitamin E is expressed as percentage of lysis by plasmin alone. Nonspecific release of radioactivity with buffer alone (289 c.p.m.) was subtracted from experimental values. Release with vitamin E alone ( $2.5 \times 10^{-5}$  M), 270 c.p.m. Experimental values (means of duplicate assays) at representative plasmin concentrations (0.6, 6 and 60 μg ml<sup>-1</sup>, values with vitamin E in parentheses): 364 (84), 6,504 (3,205) and 12,684 (11,870) c.p.m., respectively.

in the form of spontaneously activated plasminogen<sup>8</sup>, as judged by absence of generation of additional activity by appropriate streptokinase or urokinase treatment. Plasminogen and plasmin were quantitated by absorbancy at 280 nm (ref. 11). Vitamin E, in the form of D-α-tocopheryl succinate (type VI, Sigma) was suspended in Tris-NaCl buffer (0.015 M Tris, 0.15 M NaCl, pH 7.4) at a concentration of 1 mg ml<sup>-1</sup>, stirred for 15 min at room temperature, and filtered through Whatman No. 1 paper. Vitamin E content of the filtrate was quantitated by absorbancy at 292 nm (ref. 12), and colorimetrically by the tocopherol red reaction<sup>13</sup>, after preliminary alkaline saponification to yield the free phenol. Concentrations of vitamin E obtained in this way were  $3 \times 10^{-5}$  to  $4 \times 10^{-5}$  M.

Vitamin E ( $0.6 \times 10^{-5}$  M) produced 50% inhibition of fibrinolysis at a plasmin concentration of  $5 \mu\text{g ml}^{-1}$ , or  $0.6 \times 10^{-7}$  M (molecular weight of plasmin, 81,000 (ref. 14), an inhibitor-enzyme molar ratio of 100:1 (Fig. 1). Examination of the effects of varying concentrations of vitamin E (plasmin,  $5 \mu\text{g ml}^{-1}$ ) was confirmatory (Fig. 2), with 50% inhibition at a vitamin E concentration of  $0.5 \times 10^{-5}$  to  $0.6 \times 10^{-5}$  M. Sodium succinate ( $5 \times 10^{-5}$  M) or filtered buffer had no effect. Since vitamin E functions as an antioxidant<sup>1</sup>, L-cysteine hydrochloride was tested. No effect on fibrinolysis was observed at concentrations from  $10^{-7}$  to  $10^{-3}$  M. Pretreatment of assay tubes with vitamin E ( $2 \times 10^{-5}$  M,  $37^\circ\text{C}$ , 30 min) had no effect on subsequent <sup>125</sup>I-fibrin lysis. The effect of vitamin E on fibrinolysis by plasmin generated by streptokinase or urokinase activation of purified plasminogen<sup>9</sup> was identical to that with spontaneously activated plasmin. The inhibition was also

demonstrable by the fibrin plate method<sup>17</sup>, in which non-radioactive fibrin is used as substrate (Fig. 3). Finally, addition of vitamin E to urokinase-stimulated normal plasma, at concentrations producing 50% inhibition of purified plasmin, resulted in 25% inhibition of <sup>125</sup>I-fibrin lysis.

Some observed effects of vitamin E esters, particularly the phosphate, which inhibits trypsin and papain<sup>15</sup>, have been attributed to their anionic nature rather than to tocopheryl group<sup>1</sup>, and may be mimicked (in the case of inhibition of hyaluronidase) by heparin and sodium dodecyl sulphate<sup>16</sup>. Neither of these agents, tested at  $10^{-5}$  M, inhibited lysis of <sup>125</sup>I-fibrin by plasmin. Vitamin E did not inhibit lysis by four other proteolytic enzymes known to digest this substrate<sup>5,8</sup> (Table 1), at similar molar concentrations of the enzymes (maximal estimated concentrations,  $0.5 \times 10^{-7}$  M for collagenase to  $3.3 \times 10^{-7}$  M for trypsin). Additional evidence for the absence of an anionic effect has been provided by affinity chromatography experiments. D-α-tocopheryl succinate was coupled to aminohexyl Sepharose 4B (AH Sepharose, Pharmacia) by the carbodiimide reaction. With a column (1 ml bed volume) of this conjugate, in which the succinyl carboxyl group is blocked, application of purified plasmin (260 μg) resulted in binding of 80%, and subsequent elution of 60% of the bound plasmin by buffer containing D-α-tocopheryl succinate. Finally, inhibition of fibrinolysis by plasmin does not appear to be due to the ester form of the vitamin, since similar inhibition was produced by the free phenol. Pure D-α-tocopherol (Eastman Kodak), dissolved in ethanol because of its insolubility, was added to and incubated with plasmin ( $5 \mu\text{g ml}^{-1}$ , 30 min at  $37^\circ\text{C}$ ). Fifty per cent inhibition of plasmin lysis of <sup>125</sup>I-fibrin occurred at a free phenol concentration of  $1.6 \times 10^{-5}$  M, which compares with similar inhibition by the succinate ester at  $0.6 \times 10^{-5}$  M (Fig. 2). Lysis by plasmin plus ethanol (1.5% by volume) was 3,641 c.p.m., whereas lysis by plasmin in presence of D-α-tocopherol and ethanol was 1,855 c.p.m.

Reported levels of vitamin E in normal human plasma range from 6.5 to  $15 \mu\text{g ml}^{-1}$  ( $1.6$  to  $3.3 \times 10^{-5}$  M)<sup>18</sup>, concentrations greater than those producing 50% inhibition of

**Fig. 2** Effects of varying concentrations of vitamin E on lysis of <sup>125</sup>I-fibrin by plasmin ( $5 \mu\text{g ml}^{-1}$ ). Assay conditions identical to those described in the legend to Fig. 1.

Fig. 3 Effect of vitamin E on lysis of fibrin by plasmin. Plasmin (10, 30 and 100  $\mu\text{g ml}^{-1}$ ), with or without vitamin E ( $1.5 \times 10^{-5}$  M) was introduced into wells (5  $\mu\text{l}$  per well) of heat-treated fibrin plates (Enzo-diffusion plates, Hyland). Diameter of lysis was measured after incubation at 37 °C for 6 h. Semilogarithmic plot plasmin concentration against diameter of lysis, with (●) and without (○) vitamin E. Operational zero point for the assay (no detectable lysis) is 2 mm, the diameter of the wells.

plasmin *in vitro* (Figs 1 and 2). Mean plasma levels of plasminogen-plasmin, determined immunochemically, are approximately 200  $\mu\text{g ml}^{-1}$  (ref. 19). Although comprehensive data on relative proportions of proenzyme and active enzyme in normal plasma are lacking, it is generally accepted that almost all is in the proenzyme form<sup>20</sup>. In the present study, for example, plasminogen-plasmin, freshly prepared from normal plasma<sup>8</sup>, released 360 c.p.m. from <sup>125</sup>I-fibrin, representing less than 2% of the activity (18,911 c.p.m. released) of the same preparation (enzyme concentration, 5  $\mu\text{g ml}^{-1}$ ) after maximal urokinase activation. This estimated plasmin concentration (2% of 200  $\mu\text{g ml}^{-1}$ , or 4  $\mu\text{g ml}^{-1}$ ) is of the same order as the concentrations examined here, and agrees with the observations of others<sup>21</sup>. Relative to other inhibitors, vitamin E produces 50% inhibition at the same concentration (approximately  $10^{-3}$  M) as EACA or tranexamic acid (*trans*-4-aminomethylcyclohexanecarboxylic acid)<sup>8</sup>.

These observations may be pertinent to certain physiological and pathological phenomena, and to vitamin E therapy. Plasmin is normally inhibited by anti-plasmins in plasma. These include such macromolecules as  $\alpha_2$ -macroglobulin,  $\alpha_1$ -antitrypsin and C1 esterase inhibitor<sup>22</sup>. The inhibition of plasmin at physiological concentrations of vitamin E and enzyme raises the possibility that the vitamin may play a role in normal modulation of fibrinolysis. In addition, considering the broad substrate specificity of plasmin for many tissue proteins in addition to fibrin<sup>5</sup>, this effect may be relevant to foetal resorption in vitamin E deficient animals (that is, unopposed proteolytic activity), which led to the initial recognition of this vitamin<sup>23</sup>. The *in vitro* inhibition of plasmin provides an explanation for the reported blunting, on oral vitamin E therapy, of the physiological increase in fibrinolytic activity after venous

occlusion<sup>7</sup>, a response considered to reflect increased conversion of plasminogen to plasmin, mediated by tissue activators released, presumably from vascular endothelium, in response to hypoxia<sup>20</sup>. Further, fibrinolysis has been implicated in the development and spread of tumours<sup>21</sup>. Both EACA and vitamin E inhibit fibrinolysis. Administration of EACA decreases metastatic spread of transplantable tumours in rabbits and rats<sup>24</sup>, and there is a decreased incidence of carcinogen-induced lung tumours in vitamin E deficient mice when compared with normal mice, or deficient mice receiving vitamin E replacement<sup>25</sup>. Finally, in view of the widespread use of the vitamin and its succinate and acetate esters, and the observed effects of oral administration on fibrinolysis *in vivo*<sup>7</sup>, the observations presented here may have implications for the consequences of dietary supplementation with the vitamin.

## Confusion between specific and nonspecific binding of carcinoembryonic antigen and blood-group antigens by eluted antibody preparations

Cross reactivity between carcinoembryonic antigen (CEA) and blood-group antigens is inferred from the observation that many human sera can bind labelled CEA. This is more common with sera of blood group O or B (that is containing anti-A antibodies), and binding may sometimes be inhibited by absorption of the sera with group A erythrocytes<sup>1,2</sup>.

Following up these observations, Holburn *et al.*<sup>3</sup> showed that hyperimmune human antisera against A, B, Le<sup>a</sup> and Le<sup>b</sup> antigens could bind 30–75% of added labelled CEA. They concluded that the extent of binding suggested that both CEA and blood-group antigens were present on the same molecule. Freedman, commenting on these experiments, pointed out that a hyperimmune antiserum will contain many other "sticky" substances as well as antibodies, and these might account for the results (paper read at meeting of British Society for Immunology, autumn,

Fig. 1 Binding of untreated anti-A (x) and anti-B (●) to labelled \*CEA, using Farr technique for separation.

1973). To exclude any extraneous binding substances his group in Montreal used "natural" anti-A iso-antibodies, which were adsorbed on to group A erythrocytes and eluted therefrom before use. Such antibody preparations could bind at least 45% of added labelled CEA as judged by the Farr technique<sup>1</sup> and at least 11% as judged by a solid-phase technique<sup>4</sup>. We have now found that rather than removing nonspecific binding capacity from antisera, the process of adsorption to red cells and elution may increase it.

A preparation of CEA, given by Professor A. M. Neville, Chester Beatty Institute, was labelled with <sup>125</sup>I by the chloramine T method<sup>5</sup>. Human anti-A and anti-B sera were obtained from Ortho Diagnostics (lots Pearl 02N0143 and Sally 11M1219, respectively). Samples of 60 ml of each were decomplexed at 56 °C for 30 min and added to 10 ml of washed packed fresh human erythrocytes; anti-A with A cells, anti-B with B cells. After overnight incubation at 4 °C, with gentle mixing, the massively agglutinated cells were washed three times with large volumes of cold 0.9% saline. They were then mixed with an equal volume of 20% bovine serum albumin in saline and gently agitated in a water bath at 56 °C for 10 min to elute the bound antibodies. The supernates were tested by haemagglutination to confirm the presence and specificity of the antibodies.

Each solution was then divided into three equal portions; one to be adsorbed overnight at 4 °C with 10 ml washed packed A erythrocytes, one for similar absorption with group B erythrocytes and one to remain unabsorbed. The cells used for adsorption-elution and for absorption were taken from the same units of blood. Six solutions thus resulted: (1) eluted anti-A antibodies unabsorbed; (2) eluted anti-A antibodies absorbed with group A cells; (3) eluted anti-A antibodies absorbed with group B cells; (4) eluted anti-B antibodies unabsorbed; (5) eluted anti-B antibodies absorbed with group A cells; (6) eluted anti-B antibodies absorbed with group B cells.

The original anti-A and anti-B sera were used, without treatment, as further controls. Haemagglutination tests for antibody in all solutions demonstrated the presence and absence of the expected specificities.

All sera were titrated against labelled CEA, the separation

system being half-saturation with ammonium sulphate in the presence of 0.5 ml of 0.1% bovine gamma globulin. The experiment was repeated on three occasions with the same results.

Figures 1 and 2 show that fresh untreated anti-A can bind at least 30% of the CEA (16% of the binding is nonspecific) while untreated anti-B has no significant activity—if anything, binding is slightly inhibited at a high concentration of serum. After adsorption and elution, all antibody solutions bind CEA to the same extent, irrespective of any subsequent absorption.

It might be argued that the Farr technique (half-saturation with ammonium sulphate) is an inappropriate separation method for this experiment, since a constant 10–20% of CEA itself is precipitated, without any anti-serum, in the presence of a 'carrier' protein (in this case,

Fig. 2 Binding of adsorbed-eluted anti-A and anti-B to labelled CEA, using Farr technique for separation: a: ▽, Anti-A absorbed with A cells; x, anti-A absorbed with B cells; ●, anti-A unabsorbed. b: +, anti-B unabsorbed; ○, anti-B absorbed with A cells; ▽, anti-B absorbed with B cells.

Fig. 3 Binding of adsorbed-eluted anti-A and anti-B to labelled CEA, using insoluble antibody preparations. *a*: +, Anti-A unabsorbed; O, anti-A absorbed with B cells; V, anti-A absorbed with A cells. *b*: +, anti-B absorbed with B cells; O, anti-B absorbed with A cells; V, anti-B unabsorbed

bovine gamma globulin). Separation is therefore not clean and changes in binding capacity of the sera might be hidden. To answer this criticism, the six eluted antibody solutions were precipitated by 18% sodium sulphate and the globulins linked to microcrystalline cellulose (Sigma-Cell type 20) using the cyanogen bromide method<sup>6</sup>. The immunosorbents thus made were titrated against labelled CEA. Figure 3 shows that again there is no essential difference between adsorbed and unadsorbed eluates.

These results show that adsorption and elution of anti-A

from group A red cells makes no difference to its ability to bind CEA, thus confirming the results of Gold *et al.*<sup>1,4</sup>. On the other hand, absorption of this anti-A-containing eluate with group A red cells fails to reduce the binding capacity although its anti-A content becomes undetectable. This indicates that the CEA binding capacity of the eluate is not due to its anti-A activity. This conclusion is further supported by the development of CEA-binding capacity, previously absent, when anti-B is eluted from B cells. Again, this binding is not influenced by further absorption with either A or B cells.

The most likely interpretation is that human erythrocytes contain a 'sticky' non-antibody substance, extractable by heat elution, not removable by absorption with erythrocytes, which can bind to CEA. This may be the explanation for the finding<sup>7</sup> that plasma which had been stored in contact with its cells had a higher apparent CEA level than the same specimen when fresh, and the subsequent finding<sup>8</sup> that a CEA-like substance could be extracted from erythrocyte stromata. It must be remembered that the double antibody technique which was used would register a CEA-binding substance as if it were CEA.

The results reported here also throw doubt on the existence of cross reactivity between CEA and blood-group substances, since they discredit the use of erythrocyte-eluted antibodies for binding studies. Several reports favour such a negative view: (1) a monospecific anti-CEA serum does not agglutinate group A erythrocytes, and blood-group substances A and B do not inhibit CEA-anti CEA binding<sup>1</sup>; (2) *N*-acetyl-D-galactosamine, the immunodominant sugar of A antigen, is conspicuously absent from most CEA preparations<sup>4</sup>; (3) treating CEA with anti-A and anti-i immunosorbents causes no reduction in its CEA activity<sup>9</sup>; and (4) although the blood-group precursors I and i can be found in extracts of colonic cancers, they can be separated from CEA by gel filtration<sup>10</sup>.

An alternative explanation is suggested by the association of CEA with mucus and the mucous coats of cells, both neoplastic and normal (to be published). One of the most striking physical properties of mucus is its cohesiveness. A CEA-binding substance is exuded by colonic cancer cells in tissue culture<sup>2</sup>, and such cells are also known to exude CEA into the medium (as judged by techniques which do not confuse CEA-binding substances with CEA<sup>11</sup>). Erythrocytes possess a mucous coat which they shed into the plasma as they become aged<sup>12</sup>. We would suggest that both CEA and CEA-binding substance reside in mucus and in the mucous coats of cells, though not necessarily on the same molecule.

We thank Mrs P. Standart, Mr T. W. Dutton and Miss A Davies for technical assistance. This work was supported by a grant from the MRC.

## Active proton transport stimulated by $\text{CO}_2/\text{HCO}_3^-$ , blocked by cyanide

EXPOSURE of a cell to increased  $\text{CO}_2$  levels causes a drop in the intracellular pH ( $\text{pH}_i$ ) (ref. 1). The time development of this acidification has been monitored in snail giant neurones<sup>2</sup> and squid giant axons<sup>3</sup> by means of glass microelectrodes. It was found that  $\text{pH}_i$  does not simply fall to a new steady value during  $\text{CO}_2$  exposure, but, given sufficient time, will slowly recover; and that, on return to a  $\text{CO}_2$ -free solution, a higher  $\text{pH}_i$  value (more alkaline) than the initial one is attained. The slow, secondary alkalisation observed during exposure to  $\text{CO}_2$  cannot be accounted for by any passive mechanism, since the electrochemical gradients for  $\text{H}^+$ ,  $\text{OH}^-$  and  $\text{HCO}_3^-$  all favour further acidification. For example, during the alkalisation, the external pH ( $\text{pH}_o$ ) in squid axons is typically 7.7 and  $\text{pH}_i$  7.0; hence, the Nernst potentials for  $\text{H}^+$  ( $E_H$ ),  $\text{OH}^-$ , and  $\text{HCO}_3^-$  are all  $\sim -40$  mV, compared with a membrane potential ( $V_m$ ) of  $-60$  mV. Thus, a proton extruding pump, or its equivalent, must be postulated. We now report that the rate of alkalisation is at least partially dependent on the  $\text{CO}_2$  and/or  $\text{HCO}_3^-$  content of the bathing medium, that it is

**Fig. 1** Effect of  $\text{CO}_2/\text{HCO}_3^-$  buffer on pumping rate. Exposure to  $\text{NH}_4\text{Cl}$  causes  $\text{pH}_i$  to rise because of the influx and subsequent protonation of  $\text{NH}_3$ .  $\text{NH}_4^+$  is also permeant, however, and its passive influx (the Nernst potential for  $\text{NH}_4^+$  is greater than the membrane potential throughout exposure) has an acidifying effect. Thus, on return to normal ASW,  $\text{pH}_i$  is offset in the acid direction. The cell recovers from this acid load only slowly when HEPES or other non-volatile buffers are used, whereas recovery is greatly accelerated during exposure to a  $\text{CO}_2/\text{HCO}_3^-$  buffer at the same pH. The prompt acidification occurring at the onset of the  $\text{CO}_2$  exposure (segment BC) is due to the influx, hydration, and subsequent dissociation of  $\text{CO}_2$ . Removal of  $\text{CO}_2$  (segment DE) causes a reversal of these reactions, and therefore a rapid alkalisation<sup>3</sup>. The membrane potential in the post- $\text{NH}_4\text{Cl}$  period was  $-59$ – $-60$  mV; the Nernst potential for  $\text{H}^+$  varied from  $-56$ – $-48$ . In the experiment in the inset, the  $\text{pH}_o$  was 7.4 following a similar pretreatment with  $\text{NH}_4\text{Cl}$ -ASW. In HEPES-ASW the  $\text{pH}_i$  slowly falls (segment AB, rate =  $-0.03$   $\text{pH h}^{-1}$ ) while in  $\text{CO}_2/\text{HCO}_3^-$ -ASW, the  $\text{pH}_i$  rises (segment CD, rate =  $0.12$   $\text{pH h}^{-1}$ ). During the alkalisation  $V_m$  was  $-62$  mV and  $E_H$  was  $-24$ – $-17$  mV. In these experiments, axons were mounted horizontally in a chamber (temperature =  $22^\circ\text{C}$ , volume  $\approx 0.15$  ml) superfused (1 ml  $\text{min}^{-1}$ ) with ASW.  $\text{CO}_2$ -containing solutions were delivered from a glass syringe (after equilibration) through  $\text{CO}_2$ -impermeable tubing. The glass  $\text{pH}_i$  electrodes were of Hinkes's design<sup>4</sup>.

reversibly blocked by metabolic inhibitors and that an extracellular acidification accompanies the intracellular alkalisation.

These experiments were performed on giant axons of the squid *Loligo pealei*, cannulated at both ends to allow for the introduction of pH and reference electrodes. In the experiment shown in Fig. 1, an axon ( $\text{pH}_i$  7.39) was pretreated with artificial seawater (ASW) containing 50 mM  $\text{NH}_4\text{Cl}$  for  $\sim 30$  min. When, after prolonged exposure to  $\text{NH}_4\text{Cl}$ , an axon is returned to ASW, the  $\text{pH}_i$  reaches a value considerably more acid than the resting  $\text{pH}_i$  (ref. 3). In the case of Fig. 1, the  $\text{pH}_i$  fell to 7.03.

**Fig. 2** Secondary alkalisation blocked by cyanide. An axon was first exposed to 5%  $\text{CO}_2/50$  mM  $\text{HCO}_3^-$ -ASW. After the initial acidification, the axon underwent secondary alkalisation (A), on return to normal ASW, the  $\text{pH}_i$  overshoot the initial  $\text{pH}_i$  (A'). Subsequent exposure to nominally 2 mM CN caused the  $\text{pH}_i$  to fall slowly<sup>3</sup>, and to stabilise eventually over the course of 75 min. Exposure to nominally 5%  $\text{CO}_2/50$  mM  $\text{HCO}_3^-$ , CN-ASW caused the abrupt decline in the  $\text{pH}_i$ , characteristic of  $\text{CO}_2$  exposure, but led to no secondary alkalisation (B). Similarly, there was no overshoot of the  $\text{pH}_i$  when the axon was returned to CN-ASW (B'). After recovery in normal ASW, the axon once again was capable of secondary alkalisation in the presence of  $\text{CO}_2$  (C), and exhibited the characteristic overshoot on removal of the  $\text{CO}_2$  (C'). The temperature was  $22^\circ\text{C}$  throughout.

If a proton pump were designed to maintain a relatively alkaline intracellular milieu in the face of acid challenges, then one would expect the acid load following exposure to  $\text{NH}_4\text{Cl}$  to be an effective stimulus for increased pumping. Indeed, during the time segment AB, the  $\text{pH}_i$  rose, though very slowly ( $0.04$   $\text{pH h}^{-1}$ ), when  $\text{NH}_4\text{Cl}$ -free ASW was buffered at pH 8.00 with 0.5 mM HEPES. Replacement of the HEPES buffer with 0.4%  $\text{CO}_2/10$  mM  $\text{HCO}_3^-$ , keeping the seawater pH constant, however, caused the  $\text{pH}_i$  (after a small acidification due to the influx of  $\text{CO}_2$ ) to rise (segment CD) at a much greater rate ( $0.35$   $\text{pH h}^{-1}$ ). The stimulation caused by  $\text{CO}_2/\text{HCO}_3^-$  at pH<sub>o</sub> 7.4 is shown in the inset of Fig. 1. Since in both cases  $E_H > V_m$ , an active process is required to explain the observed alkalisation. In a series of 11 such experiments, the rate of intracellular alkalisation after the treatment with  $\text{NH}_4\text{Cl}$  was, at a given  $\text{pH}_o$ , always far greater in  $\text{CO}_2/\text{HCO}_3^-$ -ASW than in HEPES-ASW. The rate also increased with increasing  $\text{pH}_o$ .

The alkalisation occurring in the presence of  $\text{CO}_2/\text{HCO}_3^-$  could readily be blocked by the metabolic inhibitors cyanide (CN) and 2,4-dinitrophenol (DNP). Figure 2 illustrates an experiment in which an axon, capable of secondary alkalisation (point A) in the presence of  $\text{CO}_2$ , was exposed to CN. After  $\sim 75$  min, when the  $\text{pH}_i$  had reached a steady level, the axon was exposed to a  $\text{CO}_2/\text{HCO}_3^-$  solution in the continued presence of CN. Although typical acidification occurred, no secondary alkalisation was observed (B). Return to cyanide-free ASW and subsequent exposure to  $\text{CO}_2$  showed that the axon was once again capable of secondary alkalisation (C). Similar results were obtained with DNP.

Evidence presented so far does not rule out intracellular  $H^+$  sequestration as the cause of secondary alkalisation in the presence of  $CO_2$ . We determined that intracellular secondary alkalisation is accompanied by extracellular acidification, as follows: after pretreatment with 50 mM  $NH_4Cl$ -ASW, we placed axons in sealed capillaries containing ASW and phenol red, and followed the absorbance at 559 nm. When the ASW contained 10 mM  $HCO_3^-$  ( $pH_o$  8.0), we always observed a decrease in absorbance, corresponding to extracellular acidification; replacing the  $HCO_3^-$  with 10 mM TES ( $pH_o$  8.0;  $pK_a'$  approximately the same as for  $CO_2$ ) caused, if anything, an increase in absorbance. Again, treatment with CN prevented the characteristic absorbance decrease in the presence of  $HCO_3^-$ . Although the spectrophotometric measurements are difficult to quantify, they provide strong evidence that, as acid disappears from the cell interior, acid appears on the outside.

We acknowledge support by the NIH, and a Grass fellowship.

*Note added in proof:* Thomas<sup>5</sup> has observed that the presumed  $H^+$  pump of snail neurones, too, is more active in the presence of  $CO_2$ .

## The presence of Na-Na and Na-K exchange in sodium extrusion by three species of fish

ALTHOUGH it has been generally assumed that marine teleost fish balance the net influx of NaCl (from diffusional gain and oral ingestion of seawater) by active extrusion of both ions<sup>1-3</sup>, the proposition of active extrusion of Na has been questioned. It has been shown<sup>4-11</sup> that marine teleosts generally maintain a transepithelial potential (t.e.p.) in the range +10-+25 mV (blood relative to seawater), which is nearly equal to that which could nullify the Na concentration gradient between the teleost and seawater. Thus, it has been suggested that Na is maintained in electrochemical equilibrium across the teleost gill and only Cl is

actively extruded<sup>4,6-8,12</sup>. The Na efflux changes accompanying rapid changes in external Na or K concentrations have been used to support a model of both Na-Na and Na-K exchanges<sup>13-16</sup>, and have been shown to result at least partially from changes in the t.e.p. (refs 7-9, 12) rather than uncoupling of ionic exchange systems. Histochemical localisation of the Na-K-activated ATPase in teleost gill tissue indicates that it is predominantly basal rather than apical<sup>17,18</sup>. This suggests that the enzyme may be involved in gill cell volume regulation rather than transepithelial extrusion of Na.

Even if marine teleosts maintain blood Na in electrochemical equilibrium with seawater they face a net Na gain because of oral ingestion of the medium<sup>1,19</sup>. Also, the K-stimulated Na efflux from at least two species of marine teleosts is greater than can be accounted for by changes in the t.e.p. (refs 9, 11). Evans *et al.*<sup>16</sup> have shown that removal of K from the seawater reduces the Na efflux from *Dormitator maculatus* without affecting the t.e.p. The rapid reduction in Na efflux after transfer of a marine teleost to freshwater (or tap water) is secondary to changes in the t.e.p. (refs 7-9, 12), but Kirschner *et al.*<sup>12</sup> have shown that t.e.p. changes can only account for 60% of the fall in Na efflux from the trout, *Salmo gairdneri*, transferred from seawater to Na-free, K-free artificial seawater.

The validity of the model of Na-K and Na-Na exchange across the marine teleost gill is thus questionable, and to try to describe the components of Na efflux from marine teleost fish more clearly, we investigated the kinetics of Na efflux and the changes in t.e.p. in three species of teleosts, *Achirus lineatus* (lined sole), *Hippocampus erectus* (lined seahorse) and *Opsanus beta* (gulf toadfish) in seawater and other electrolyte solutions. All specimens were collected by us on commercial shrimp trawlers in Biscayne Bay, Florida. They were maintained in seawater (500 mM  $Na^+$ ) in 30-gallon glass aquaria at  $22 \pm 1^\circ C$  for at least 1 week before experimentation and were fed either TetraMin (Tetra Werke) or live brine shrimp until 24 h before an experiment. The techniques for determination of rapid changes in unidirectional Na efflux and t.e.p. have been described<sup>9,16</sup>. The only modification was that the t.e.p. was determined on unanaesthetised and submerged sole and toadfish, the seahorse was anaesthetised lightly ( $4 \times 10^{-3}$  g per 1 MS-222) and held with the head and opercula submerged and the site of bridge implantation above the water level. Fluxes and t.e.p. were measured in separate experiments and the fish were either transferred from seawater to tap water or from seawater to K-free, Na-free seawater (-K, -Na SW) and

Table 1 Effect of ion-free solutions on the unidirectional Na efflux and the t.e.p. across three marine teleosts

Species	Na efflux			
	SW	TW	-K, -Na SW	25 K, -Na SW
<i>A. lineatus</i>	100	$46 \pm 3$ (7)*	$18 \pm 4$ (6)*	$29 \pm 4$ (6)†
<i>H. erectus</i>	100	$36 \pm 1.4$ (5)*	$19 \pm 2$ (13)*	$27 \pm 3$ (13)†
<i>O. beta</i>	100	Unstable (10)‡	$11 \pm 3$ (7)	$28 \pm 2$ (7)†
t.e.p.				
<i>A. lineatus</i>	$-6.8 \pm 0.6$ (20)	$+5.5 \pm 1.4$ (6)*	$-15 \pm 0.6$ (5)*	$-15 \pm 0.9$ (5)
<i>H. erectus</i>	$-3.5 \pm 0.4$ (14)	$-1.9 \pm 1.9$ (9)*	$-9.2 \pm 0.4$ (14)*	$-9.3 \pm 0.7$ (14)
<i>O. beta</i>	$-8.1 \pm 0.9$ (12)	Unstable (6)‡	$-15 \pm 1.5$ (6)	$-15 \pm 1.5$ (6)

All data are expressed as mean  $\pm$  s.e., number of experiments in parentheses. All flux values are expressed as a % of the control efflux when the animal is in seawater. The t.e.p. is expressed as blood relative to medium (mV).

\* Significantly different ( $P \leq 0.005$  in paired experiments) from the seawater control.

† Significantly different ( $P \leq 0.005$  in paired experiments) from the -K, -Na SW data. -K, -Na SW: 2.5 mM  $Na^+$ , 571 mM  $Cl^-$ , 53 mM  $Mg^{2+}$ , 10 mM  $Ca^{2+}$ , 28 mM  $SO_4^{2-}$ , 2.5 mM  $HCO_3^-$ , 501 mM choline<sup>2+</sup>. 25 K, -Na SW; same as above except that 25 mM  $K^+$  is added as the sulphate salt.

‡ Effluxes and t.e.p. of *O. beta* in tap water are unstable but show the same trends as displayed in the other two species. In tap water the sodium efflux falls to  $32 \pm 2.7\%$  of the seawater control but within 3-5 min increases to  $81 \pm 5.5\%$  of the control. In tap water the t.e.p. always depolarises (range -1 to +16 mV) immediately, but within 10 min falls back towards the t.e.p. in seawater and stabilises at a t.e.p. usually somewhat depolarised from the seawater control (range -6 to +6 mV).

then into 25 mM per l K-enriched, Na-free seawater (25 K, -Na SW).

The results are shown in Table 1. All three species maintain their blood distinctly negative to seawater and this is the first description of a marine teleost with t.e.p. blood negative to seawater. Although we did not determine blood Na concentrations in our animals, all marine teleosts have a blood Na concentration well below that of seawater<sup>20</sup> so it seems that, unlike other teleosts, *A. lineatus*, *H. erectus* and *O. beta* face a substantial electrochemical gradient for Na across their epithelium. They all display a significant reduction in Na efflux and change in t.e.p. after transfer to tap water. In all cases, however, the t.e.p. becomes less negative rather than more negative as has been described for other teleosts<sup>7-9,12</sup>. Obviously, changes in the t.e.p. cannot account for the observed reduction in unidirectional Na efflux from these species in tap water. So it seems that the decline in unidirectional Na efflux is secondary to an uncoupling of Na-K and/or Na-Na exchange rather than a change in passive efflux. Tap water, however, is not only Na- and K-free but also free of other ions (for example, Ca, Mg) that may be important in maintenance of the normal marine teleost gill epithelium, and it has been shown that external Ca has profound effects on the fluxes of Na and Cl as well as the t.e.p. in both the freshwater goldfish, *Carassius auratus* and the marine mullet, *Mugil capito*<sup>21,22</sup>. Thus, it is more relevant to measure the flux and t.e.p. changes after transfer from SW to -K, -Na SW rather than to tap water. In all three species, transfer to -K, -Na SW results in a 6-8-mV increase in the internal negativity and an 80-90% reduction in unidirectional Na efflux. Although the change in the t.e.p. could account for a 10% reduction in Na efflux (see refs 9 and 12 for relevant formulae), it cannot account for the reduction seen experimentally.

The discrepancy between the data in tap water and -K, -Na SW should be noted (especially for *O. beta*). With the exception of that by Kirschner *et al.*<sup>14</sup>, other studies of flux and t.e.p. changes in ion-free media have involved the use of tap or freshwater. It can be seen from our work that transfer of a marine teleost to tap water may alter the permeability characteristics of the gill epithelium sufficiently to produce spurious results.

Thus, our data clearly show that the majority of the unidirectional Na efflux from three marine teleosts is coupled to the external K and/or Na concentration exclusive of t.e.p. changes. Data in Table 1 show clearly that, after transfer from -K, -Na SW to 25K, -Na SW, although the t.e.p. does not change, the Na efflux increases in all three species. Thus, Na-K exchange does occur in Na extrusion in these teleosts but (since even 25 mM K l<sup>-1</sup> results in an Na efflux of only 30% of the Na efflux in seawater) is a relatively minor component compared with diffusional efflux and Na-Na exchange. In summary, *A. lineatus*, *H. erectus*, and *O. beta* maintain their blood Na out of electrochemical equilibrium with seawater Na and extrude the excess Na by way of an Na-K exchange mechanism. In addition, Na-Na exchange diffusion is important in the unidirectional Na efflux from these species.

## Roles of carbonyl oxygens at the bilayer interface in phospholipid-sterol interaction

FROM many recent studies on the phospholipid-sterol interaction, it has become increasingly clear that the 3  $\alpha$ - and 3  $\beta$ -hydroxy isomers of a range of sterols have quite different effects on the molecular mobility and functional property of lipid bilayer membranes<sup>1,2</sup>. For example, the addition of cholesterol or  $\Delta^5$ -cholesten-3  $\beta$ -ol to liposomes decreases their permeability, whereas epicholesterol, a 3  $\alpha$ -isomer of cholesterol, exerts no apparent effect. It has been proposed that the 3  $\beta$ -hydroxyl group engages in hydrogen bonding with the carbonyl oxygen of the fatty acyl groups in phospholipids in the bilayer<sup>1</sup>. Evidence supporting such hydrogen bond formation is strong<sup>4</sup>. The problem is, then, why does the 3  $\beta$ -OH group of cholesterol, but not the 3  $\alpha$ -OH group of epicholesterol form such bonds?

Here I first discuss the molecular configuration of the bilayer interface and its characteristics, and then propose molecular models to describe hetero-intermolecular hydrogen bonds between the carbonyl groups of phospholipids, hydroxyl groups of sterols, and water molecules in the bilayer interface, which enable rationalisation at the difference in activity between the 3  $\alpha$ - and 3  $\beta$ -hydroxy isomers of sterols.

Fig. 1 Schematic diagram showing the planarity of the structural

of a phospholipid molecule and the

hydrocarbon surface of the bilayer. Values of various bond angles are taken from the crystal structure of acetylcholine<sup>5</sup>.

The small region taken up by the structural element

of phospholipids in the bilayer is termed the bilayer interface. Here, C1 and C2 are, respectively, the first and second carbon atoms of the fatty acyl chain. Several aspects of the geometry of the elements are pertinent. First, a plane passing through all the C2 carbons of the acyl chains can be considered as the hydrocarbon or non-polar surface of the bilayer (Fig. 1). Second, the carbonyl double bond and the partial double bond character of the ester C-O bond cause all carbon and oxygen atoms in the structural element to be coplanar<sup>5,6</sup>, similar to the atomic arrangements found in the amide plane of polypeptide chains and sphingolipids. Moreover, the C-H bond of the secondary ester is synplanar to C1=O as shown in Fig. 1<sup>6,7</sup>. Because of this planarity of the structural element, the segmental motions of carbon atoms in the bilayer interface are expected to be rather restricted. Indeed, <sup>13</sup>C-NMR (nuclear magnetic resonance) experiments demonstrate that the spin-lattice relaxation times of carbon nuclei within the phosphatidylcholine molecule in a bilayer increase from the glycerol backbone to both the methyl ends of the two fatty acyl chains and the -N<sup>+</sup>(Me)<sub>3</sub> end of the polar head group, indicating the smallest segmental mobility of the carbon atoms in the structural element<sup>8,9</sup>. Finally, on the basis of the planarity of the structural element together with the vertical orientation of the two parallel fatty acyl chains away from the hydrocarbon surface in the liquid crystalline state<sup>10</sup>, it is reasonable to assume that the C1=O bond adopts a tilted orientation with respect to the hydrocarbon surface as shown in Fig. 1. In spite of the uncertainty in the precise orientation of the carbonyl groups, it is important to point out that the carbonyl group is held rigidly in proximity to the hydrocarbon phase of the bilayer which has a low dielectric constant.

In discussing the carbonyl oxygen in the bilayer interface serving as a hydrogen bond acceptor, two features of hydrogen bonds must be considered. In the first place, of 196 hydrogen bond angles studied, the configuration of O-H...O bond angles which appeared with the greatest frequency was found to be approximately 15° from the linear configuration<sup>11,12</sup>. In other words, a stable hydrogen bond has such a configuration that the donor, hydrogen, and acceptor atoms are nearly colinear. Second, the hydrogen bond is electrostatic in origin, with greater strength in a medium of low dielectric constant. The intrapeptide hydrogen bonds, for example, do exist in the interior of proteins where the effective dielectric constant is relatively low.

A plausible model for a phospholipid-cholesterol complex at the interface of a bilayer is presented in Fig. 2a, showing how the equatorial hydroxyl group on C3 can satisfy the necessary conditions for hydrogen bond formation. The rigid, planar fused ring system of the molecule

is inserted vertically into the hydrocarbon core with C3 at the hydrocarbon surface, bringing the more polar hydroxyl group into the interface, where the dielectric constant is still sufficiently low to enhance the formation of a hydrogen bond.

It is not likely that water can displace and thus compete with cholesterol for the formation of stable hydrogen bonds to carbonyl oxygens at the same binding site as shown in Fig. 2a, because the necessary orientation would bring water molecules near the hydrocarbon phase, an energetically improbable circumstance. Water molecules may, however, form bonds by orientating themselves in solution towards the polar surface of the bilayer. This possibility would be favoured by the presence of cholesterol, which increases the separation of head groups on the phospholipid molecules<sup>13</sup>, and therefore also increases the configurational freedom of water molecules in the upper portion of the bilayer interface. Thus, my model predicts that no more than one molecule of water will form hydrogen bonds with each carbonyl oxygen atom of the bilayer (two per molecule of phospholipid) in any event, and bonding may be even more difficult in the absence of cholesterol.

The model explains why sterols with the 3α configuration lack activity in membrane functions. Figure 2b illustrates the orientation of epicholesterol, the 3α isomer of cholesterol, when it is positioned so as to bring the hydroxyl group into the interface; Fig. 2b shows that the O-H...O bond angle is approximately 55°, too great for effective hydrogen bonding<sup>12</sup>. Lowering the sterol so as to bring carbon 3 to the same level as that shown for cholesterol has the effect of not only increasing the distance between the OH group and the carbonyl oxygen which is unfavourable for hydrogen bond formation, but also partially embedding the hydroxyl oxygen atom into the hydrocarbon region of the bilayer which is energetically unfavourable.

In summary, I believe the key difference between the effect of cholesterol and epicholesterol on the bilayer structure and function lies in their hydrogen-bonding abilities toward the carbonyl group of the ester linkage of the acyl side chains of phospholipids. This difference is a natural consequence of the constrained orientation of these carbonyl oxygen atoms. It is well known that the polar head group of cholesterol molecule may dictate the orientation of the whole molecule in the monolayer<sup>14</sup>. I would like to point out that the hydrogen-bonded structural effect of cholesterol may also lead to long range effects on the packing density of the hydrocarbon chains of neighbouring phospholipids. Such changes in hydrocarbon packing would be expected to affect the permeability properties of the bilayer membrane<sup>1</sup>. Furthermore, a simple substitution of the hydrogen bond donor from cholesterol shown in Fig. 2a to proteins affords a reasonable extension of the molecular model to explain some of the lipid-protein interaction. In fact, <sup>13</sup>C chemical shifts of carbonyl groups of different classes of lipoproteins have been reported<sup>15</sup>. These observed chemical shifts are consistent with a molecular model in which carbonyl oxygens of lipids are engaged in hydrogen bonding to water molecules and other membrane components<sup>3</sup>.

I thank Professor R. W. McGilvery for encouragement and other colleagues for critical comments. This research was supported by a grant from the US Public Health Service.

## Effect of prostaglandin synthesis on renal function and renin in the dog

THERE is considerable evidence for an interrelationship between the prostaglandin and renin-angiotensin systems in the kidney. Infusion of angiotensin II into the renal arteries of dogs and rabbits releases a vasodilator prostaglandin-like material into the renal vein<sup>1-4</sup>. It also seems that prostaglandins (PGs) induce renin release in the kidney. Riley and his coworkers<sup>5,6</sup> infused PGE<sub>1</sub> in to the dog renal artery and observed increases in plasma renin activity (PRA) of renal vein blood and in renin secretion. Elevated PRA was observed in blood from the inferior vena cava, just above the entrance of the renal vein, after aortic infusions of PGE<sub>1</sub> (ref. 7) and infusion of PGE<sub>1</sub> and PGA<sub>1</sub> in to the stenosed renal arteries of hypertensive dogs, caused an elevation of renal vein renin<sup>8</sup>. PGE<sub>2</sub> was shown to stimulate renin release in a rabbit renal cortex cell suspension<sup>9</sup>. Indomethacin decreased the PRA of normal and hypertensive rabbits<sup>10,11</sup>, and prevented the elevation of PRA in rabbits with glycerol-induced acute renal failure<sup>12</sup>. In contrast, however, Vander<sup>13</sup> infused both PGE<sub>1</sub> and PGE<sub>2</sub> into the dog renal artery and failed to observe an effect on renin output.

More recently, Larsson *et al.*<sup>11</sup> infused sodium arachidonate, the precursor of PGE<sub>2</sub> and PGF<sub>2α</sub>, into the descending aorta of the rabbit and observed elevated PRA in blood from the

inferior vena cava. Their control PRA levels were, however, abnormally high (which they attributed to the anaesthetic), and neither renin secretion, urinary parameters, nor renal vein PG levels were measured during the sodium arachidonate infusion. Anggard and Larsson<sup>14</sup> stimulated renin release by the addition of arachidonic acid to an *in vitro* rabbit kidney preparation. In our study we examined the effects of sodium arachidonate-induced changes in renal function on renin output.

The increased renal blood flow (RBF) caused by the infusion of sodium arachidonate is shown in Table 1. There were no significant changes in the mean glomerular filtration rates (GFR) of the three infusion periods or the GFR of the three urine collections in the sodium arachidonate period. Since the GFR was not altered, the calculated filtration fraction decreased, suggesting predominantly efferent arteriolar dilatation. The increase in RBF occurred in the absence of any systemic effects and was characterised by a delay in onset of 31.5±18.2 s (s.e.m., *N* = 11). Coincidental with the increase in RBF there was a marked diuresis and natriuresis. In the first control period the urinary flow rate and sodium excretion rate for the right kidney were lower than those of the left. This is probably the result of surgical trauma, because the right kidney was unavoidably manipulated and the left kidney was untouched. The contralateral kidney demonstrated no significant alterations during the infusion of sodium arachidonate. The haemodynamic, diuretic and natriuretic responses are similar to those reported by others who infused PGE<sub>2</sub> and sodium arachidonate into dog renal arteries<sup>15,16</sup>. Accompanying the urinary and RBF changes were significant increases in renal vein PRA, renin secretion and renal vein PGF material. The PGF levels were used as indicators of increased activity of the arachidonate-prostaglandin system, since sodium arachidonate has been shown to stimulate synthesis and release of both PGE and PGF by the kidney<sup>15,17</sup>.

All responses to sodium arachidonate infusion were markedly attenuated by pretreatment with indomethacin. The inhibition by indomethacin of the sodium arachidonate-induced elevation

Table 1 Effects of sodium arachidonate on renal function in dogs

The effects on renal function of sodium arachidonate in salt-loaded dogs and salt-loaded dogs pretreated with indomethacin (PI). Values are given as the mean ± s.e.m. Number in parentheses are the number of animals. R, Right (infused) kidney; L, left (control) kidney;  $\dot{V}$ , urinary flow rate;  $U\dot{V}_{\text{Na}^+}$ , urinary sodium excretion rate; FF, filtration fraction; \**P* < 0.001; †*P* < 0.01; ‡*P* < 0.05. Twenty-three female mongrel dogs were fasted 18 h before surgery and allowed free access to water. Anaesthesia was induced by intravenous pentobarbital. Indwelling polyethylene catheters were inserted into the right and left femoral arteries for monitoring systemic blood pressure and collecting blood samples, respectively. A catheter was also placed in the left femoral vein and advanced into the right renal vein. A fourth catheter was placed in the right femoral vein for the infusion of inulin. A suprapubic midline abdominal incision was made and both ureters cannulated. A right retroperitoneal flank incision was made, and a pneumatic cuff and electromagnetic flowprobe were placed around the renal artery. The pneumatic cuff was used to establish and verify the electronic zero flow. RBF was monitored by a sine wave, non-occluding electromagnetic flowmeter (Biotronex Laboratories). A 25 gauge infusion needle was inserted into the right renal artery, normal saline was infused at 0.5 ml min<sup>-1</sup>. The animals received an intravenous saline load of 10% body weight, after which the intravenous saline infusion was matched to the urine output of 0.5-2.0 ml min<sup>-1</sup>. Seven animals received an intravenous injection of indomethacin at a dose of 10 mg kg<sup>-1</sup> buffered to pH 7.4. One hour was allowed before the commencement of the experiment. The study was comprised of three 30-min periods; three 10-min urine collections were obtained during each period. Midway through each period arterial and renal vein samples were collected for inulin, sodium, renin and PGF determinations. After the first control period, sodium arachidonate<sup>28</sup> (Nu Chek Prep) was infused into the renal artery, delivering 25  $\mu\text{g}$  per kg body weight per min. Thirty minutes was allowed for renal function to return to control levels and then the final control period was begun. The animals were killed and the kidneys removed and weighed. Renin and PGF levels were determined by radioimmunoassay. The level of significance was determined by the paired Student's *t* test.

in renin secretion indicates that sodium arachidonate is not active *per se* but must be converted to another compound, such as one of the intermediary endoperoxides, thromboxane  $A_2$  and/or PGs.

There are several possible explanations for the observed increase in renin release. Both renal nerve stimulation and the infusion of catecholamines into the renal circulation enhance renin release<sup>18,19</sup>, and PGF has been shown to potentiate adrenergic activity<sup>20,21</sup>. Frame *et al.*<sup>22,23</sup>, however, observed that PGE<sub>2</sub> and sodium arachidonate attenuate renal sympathetic transmitter release and vascular responses to noradrenaline in the rabbit kidney. Therefore, it is doubtful that the sympatho-adrenal system is involved in the sodium arachidonate-induced renin release. Riley *et al.*<sup>5</sup>, concluded that the PGE<sub>1</sub>-induced elevation of renin output was due to vasodilatation and physical distortion of the juxtaglomerular apparatus. Tagawa and Vander<sup>24</sup>, however, found that vasodilatation induced by acetylcholine had no effect on renin release. Furthermore, Witty *et al.*<sup>25</sup> observed no significant alterations in renin secretion when papaverine, a potent vasodilator, was infused into the renal artery of the denervated non-filtering kidney, the denervated filtering kidney and the innervated non-filtering kidney of the dog. This suggests that renal vasodilatation or juxtaglomerular apparatus distortion do not necessarily result in increases in renin secretion. In addition, several investigators have shown that decreases in renal perfusion pressure which result in decreased afferent arteriolar stretch stimulate renin secretion<sup>26,27</sup>. Werning *et al.*<sup>7</sup> and Varkarakis *et al.*<sup>8</sup> attributed the stimulation of the renin-angiotensin system by PGE<sub>1</sub> to alterations in the sodium concentration in the tubular urine acting through the macula densa. In contrast, Tagawa and Vander<sup>24</sup> demonstrated that acute water and electrolyte losses induced by renal vasodilatation did not result in elevations in renin secretion. These observations indicate that distortion of the juxtaglomerular region, changes in sodium flux at the macula densa or adrenergic stimulation are not primarily responsible for the increase in renin release seen with the infusion of sodium arachidonate. PGE<sub>2</sub> and arachidonate stimulation of renin release in the *in vitro* rabbit kidney preparation also argue against these theories. We, therefore, favour the concept that the arachidonate-PG system stimulates renin secretion by a direct action on the juxtaglomerular apparatus in the intact animal.

## Interaction of tryptophan transfer RNA with Rous sarcoma virus 35S RNA

THE primer for the initiation of DNA synthesis by the RNA-directed DNA polymerase (reverse transcriptase) on Rous sarcoma virus (RSV) 70S RNA has been identified as tryptophan tRNA<sup>1,2</sup>. The RNA primer hybridises efficiently to 35S RNA subunits produced by denaturation of 70S RNA from RSV<sup>3</sup> or avian myeloblastosis virus (AMV)<sup>4</sup>; these template-primer complexes are active in the initiation of DNA synthesis by reverse transcriptase<sup>3-5</sup>.

**Fig. 1** Isolation of 35S RNA-tRNA<sup>Trp</sup> hybrids by sucrose density gradient centrifugation. Prague C RSV 35S RNA (125 µg) was hybridised with <sup>32</sup>P-tRNA<sup>Trp</sup> (26 µg; 70,000 c.p.m. µg<sup>-1</sup>) according to the procedure of Waters *et al.*<sup>4</sup>. The hybridisation mixture was subjected to centrifugation in a 15-30% (w/v) sucrose density gradient as described previously<sup>12</sup>. The radioactivity in each fraction was monitored by Cerenkov radiation and the fractions comprising the high molecular weight RNA region (shaded area) were pooled and precipitated with ethanol<sup>12</sup>. RSV RNA was prepared as described previously<sup>12</sup>. Uniformly labelled <sup>32</sup>P-tRNA<sup>Trp</sup> was isolated by two-dimensional electrophoresis<sup>13</sup> from the free 4S RNA fraction of <sup>32</sup>P-labelled RSV. The identity and purity of tRNA<sup>Trp</sup> was established by fingerprint analysis (see Fig. 3a). Non-radioactive RSV (Prague C) was obtained through the courtesy of Dr R. E. Smith from University Laboratories, Highland Park, New Jersey, under the auspices of the Office of Program Resources and Logistics, National Cancer Institute.

**Fig. 2** Autoradiogram of the polyacrylamide gel fractionation of a 35S RNA-tRNA<sup>Trp</sup> hybrid RNase T<sub>1</sub> digest. P, Position of undigested tRNA<sup>Trp</sup> determined from a parallel electrophoretic run; B, position of bromophenol blue tracking dye; O, origin. Electrophoresis was from top to bottom. RNA hybrids, prepared as described in the legend of Fig. 1, were dissolved in 100  $\mu$ l of 0.01 M Tris-HCl, pH 7.5-0.1 M NaCl. RNase T<sub>1</sub> (Sankyo Co., Japan; obtained from Calbiochem Corp.) was added to give a final concentration of 0.83 U per 100  $\mu$ g RNA. After 30 min at 37 °C, the digest was rapidly cooled, diluted with two volumes of electrophoresis buffer (0.045 M Tris, 1.4 mM EDTA, 0.045 M boric acid, pH 8.3) and subjected to electrophoresis in a 10% polyacrylamide gel<sup>13</sup>. Those areas of the gel containing <sup>32</sup>P-RNA were excised and the RNA eluted as described previously<sup>11</sup>. In the case of small oligonucleotides (area 3), the gel was crushed and suspended in electrophoresis buffer. The radioactive material was then recovered by electrophoresis on to DEAE paper<sup>7</sup>.

We have examined the nature and extent of the interaction between tRNA<sup>Trp</sup> and RSV 35S RNA by characterising fragments of tRNA<sup>Trp</sup> which result from limited digestion of 35S RNA-tRNA<sup>Trp</sup> hybrids with RNase T<sub>1</sub>. The large, undigested fragments of tRNA<sup>Trp</sup> represent regions of the polynucleotide chain which are complementary to the 35S RNA. Earlier studies on bacteriophage RNAs have shown that, in the appropriate conditions, guanylate residues normally susceptible to the action of RNase T<sub>1</sub> are resistant to digestion when base paired in regions of secondary structure<sup>6-8</sup>.

<sup>32</sup>P-tRNA<sup>Trp</sup> was hybridised to non-radioactive 35S RNA. The resulting hybrids were separated from uncomplexed tRNA<sup>Trp</sup> by sucrose density gradient centrifugation (Fig. 1). After recovery by ethanol precipitation, the hybrids were dissolved in a buffer of high ionic strength to stabilise the interaction between the polynucleotide chains, then digested with RNase T<sub>1</sub>. The digestion products were fractionated by polyacrylamide gel electrophoresis (Fig. 2).

Digestion of the 35S RNA-tRNA<sup>Trp</sup> complex resulted in the release of two components which moved more slowly than free, undigested tRNA<sup>Trp</sup> (bands 1' and 1, Fig. 2) and smaller components which had mobilities greater than tRNA<sup>Trp</sup> (band 3, Fig. 2). In some digests an additional component was often present; although not apparent in the digest represented in Fig. 2, its position of migration is indicated as band 2. When unhybridised tRNA<sup>Trp</sup> was digested in the presence of 35S RNA using the same digestion conditions used for the 35S RNA-tRNA<sup>Trp</sup> complex, radioactive material was detectable in the position of band 3, but not in the positions of bands 1', 1 or 2.

The radioactive fragments comprising bands 1', 1 and 2 were completely digested with RNase T<sub>1</sub> and the products of digestion were fractionated either by one- or two-dimensional electrophoresis. Figure 3 shows the fractionation patterns obtained for bands 1', 1, and tRNA<sup>Trp</sup>. The fractionation pattern obtained for band 2 was identical to that of band 1; band 2 presumably results from partial dissociation of the double-stranded RNA complex (band 1) during dilution in the electrophoresis buffer before electrophoresis.

The oligonucleotides resolved by electrophoresis were identified by comparing their pancreatic RNase digestion products with the pancreatic RNase digestion products of the oligonucleotides obtained from the complete RNase T<sub>1</sub> digestion of intact tRNA<sup>Trp</sup>.

Since the nucleotide sequence of tRNA<sup>Trp</sup> has been determined<sup>1</sup>, it is possible to determine from which region of the tRNA the oligonucleotides released by RNase T<sub>1</sub> were derived. All the oligonucleotides present in bands 1', 1, and 2 are derived from the 3' end of the molecule (Fig. 4). This region of the tRNA must therefore be complementary to the 35S RNA. The analysis of material in the area of the

**Fig. 3** Electrophoretic separation of complete RNase T<sub>1</sub> digests of fragments of 35S RNA-tRNA<sup>Trp</sup> hybrid complexes. *a* and *b*, Fractionation<sup>14,15</sup> of digests of tRNA<sup>Trp</sup> (control) and band 1', respectively. 1, Direction of electrophoresis in the first dimension; 2, direction of electrophoresis in the second dimension. *c*, One-dimensional fractionation on DEAE paper of a digest of band 1. B, Position of the xylene cyanol blue marker; G, guanosine 3'-phosphate. The oligonucleotide numbering system is identical to the system of Faras *et al.*<sup>1,16</sup>. Oligonucleotide 13' results from the rearrangement of m<sup>3</sup>A to m<sup>6</sup>A in oligonucleotide 13.

**Fig. 4** tRNA<sup>Trp</sup> fragments resistant to RNase T<sub>1</sub> digestion in 35S RNA-tRNA<sup>Trp</sup> complexes. The nucleotide sequence of tRNA<sup>Trp</sup> and the numbering system of the oligonucleotides have been described previously<sup>1,16</sup>. \*, Modified nucleotides. Solid lines under a nucleotide sequence indicate regions protected from digestion with RNase T<sub>1</sub>.

gel designated as band 3 showed only the presence of oligonucleotides derived from the 5' end of the tRNA (data not shown).

The finding that the 3' end of the tRNA<sup>Trp</sup> molecule is complementary to the 35S RNA is not surprising in view of the fact that polymerisation by reverse transcriptase results in the covalent linkage between the terminal 3'-OH adenosine of the primer RNA and the first deoxyadenosine residue of the nascent DNA<sup>9-11</sup>.

It seems likely that the interaction of tRNA<sup>Trp</sup> with viral RNA would still allow for the formation of both the anticodon and dihydro U loops as well as the maintenance of the anticodon arm portion of the 'L'-shaped tertiary conformation<sup>17</sup>. In addition, the 3' end of the tRNA may interact with the viral RNA so as to maintain the overall symmetry of the tRNA. The symmetry of the complex might be important with respect to its recognition by reverse transcriptase<sup>18</sup>.

We thank Dr R. E. Smith for supplying cultures of RSV transformed chick embryo fibroblasts, Dr S. H. Kim for discussions, and Carol Lubbers for technical assistance. This work was supported by a grant from the US National Institute of Allergy and Infectious Diseases. J.N. holds a Faculty Research Award from the American Cancer Society.

## 11-*cis* vitamin A in dark-adapted rod outer segments is a probable source of prosthetic groups for rhodopsin biosynthesis

THROUGHOUT life, the outer segments of rod photoreceptors (ROS) are renewed continually<sup>1</sup>, a process that entails

assembly of new disk membranes at the base of the ROS. Biosynthesis of the apoprotein of rhodopsin, the major membrane protein of the ROS disks, is known to occur in several stages in the inner segment<sup>2-5</sup>. Bok has found, however, that completion of the rhodopsin molecule by combination with its retinaldehyde prosthetic group does not take place until after the apoprotein has been transported to the ROS<sup>6</sup>, perhaps just before its insertion in to the membrane. The process continues unimpaired in darkness<sup>7,8</sup>, so that in these conditions a pool of 11-*cis* vitamin A should be readily available close to the site of synthesis.

Frogs (*Rana pipiens*, southern variety) were dark adapted for 24 h at 25 °C. The retinæ were cleanly dissected in Ringer solution, any small areas with adhering pigment epithelium being cut away and discarded. Wherever possible, all subsequent operations were carried out in a nitrogen atmosphere with nitrogen-purged solvents. The retinal material was separated into two fractions by syringing through a No. 17 trochar to shear off the ROS and centrifuging on a discontinuous sucrose gradient according to Papermaster and Dreyer<sup>9</sup>. The ROS were quantitatively collected and pelleted in water. Attempts at further purification always resulted in appreciable loss of vitamin A. The residual ROS-denuded retina was washed with water. Subsequent rhodopsin extractions with 2% digitonin indicated that 90% of the ROS had been removed by this procedure.

The tissue fractions were freeze-dried and powdered thoroughly, and the vitamin A extracted by grinding three times with aliquots of light petroleum (b.p. 37-48 °C). A further small quantity of vitamin A could be extracted if the residues were mixed with water, methanol and then light petroleum, but it amounted to only 8-10% of the total. The methanol treatment destroys rhodopsin, however, so appreciable amounts of retinaldehyde were also present.

It was found that the ROS contained a small, but measurable, supply of vitamin A and that it differed markedly in both isomeric configuration and degree of esterification from that found elsewhere in the retina. After filtration (Millipore FHLPO 1300) and concentration to equal volumes, the light petroleum extracts were chromatographed by high pressure liquid chromatography (HPLC; see legend to Fig. 1 for details)<sup>10</sup>. Retinyl esters eluted first and were followed several minutes later by retinol isomers. The separated ester and alcohol fractions were quantitatively transferred to 0.1 ml of dry chloroform. One drop of acetic anhydride was added, followed by 0.9 ml of Carr-Price reagent (saturated solution of SbCl<sub>3</sub> in chloroform). Spectra of the blue colour generated by this reaction are shown in Fig. 1a and b. The  $\lambda_{\max}$  are at 620 nm, and the absorbance depends on the amount of vitamin A present, irrespective of its isomeric configuration and whether it is esterified or not<sup>11</sup>.

The ROS-denuded retina accounted for about half of the total vitamin A, most of it (82%) being in the form of ester. On the other hand, the alcohol predominated (82%) in the ROS, which distinguished them not only from the rest of the retina but also from the pigment epithelium<sup>10,12,13</sup>. The vitamin A in this tissue is almost entirely esterified in the yellow oil droplets and 92% in the cytoplasm<sup>14</sup>.

**Fig. 1** Vitamin A content of ROS compared with the rest of the retina. *a* and *b* show the spectra of the Carr-Price "blues" (Cary 14 spectrophotometer) from the retinyl ester and retinol fractions separated by HPLC as summarised below. Both colour intensity and  $\lambda_{\max}$  are independent of isomer configuration and whether alcohol or ester forms are involved<sup>11</sup>. The ROS contained 3.69 nmol vitamin A of which only 0.69 nmol was ester. From the rest of the retina the yield was 3.48 nmol, of which 2.86 was ester. *c* and *d* show the HPLC records obtained. Retinyl esters eluted between 3.5 and 7.0 min. Other absorbing substances, including small amounts of carotenoid esters, appeared during this time but did not interfere with the Carr-Price reaction. For clarity, the initial peak of the HPLC record has been blocked out. The 11-*cis* and all-*trans* retinols eluted between 9.5 and 16.0 min. The minor peak preceding 11-*cis* in the ROS extract was not identified; its size varied between different experiments. The experimental conditions were: Columns, 2 m  $\times$  2 mm stainless steel packed with Corasil II (Waters Associates), eluant, 1% isopropanol in hexane (Fisher H-291), flow rate, 0.9 ml min<sup>-1</sup> from a Waters model 6000 pump; detection, 310 nm at absorbance 0.05 setting on an Instrument Specialties model UA-5 monitor; injection, 24  $\mu$ l, Chromatronic fixed-loop valve. Recovery of retinol from the column averaged 95%, retinyl ester 100%. *a*, *c*, Retina without ROS; *b*, *d*, ROS.

As Fig 1*b* and *c* shows, the alcohol fractions eluted in two bands maximal at 10.6 and 13.0 min identified respectively as 11-*cis* and all-*trans* retinol<sup>10</sup>. The 11-*cis* isomer accounted for as much as 60% of the ROS retinol, but the all-*trans* isomer preponderated in the small quantity of retinol present in the remainder of the retina.

The vitamin A content of the ROS amounts to 4.2 mol % of the rhodopsin, determined by digitonin extraction of the light petroleum-extracted residues. This corresponds to about a 2-d supply of prosthetic groups if ROS growth proceeds at the rate of  $\sim 2\% \text{ d}^{-1}$  (ref. 1). The amount of 11-*cis* retinol alone is thus sufficient to sustain rhodopsin renewal for about 1 d. Normally, the pool of ROS retinol would be continually replenished, probably from supplies in the pigment epithelium which are known to amount to about 2 mol of retinyl ester per mol of retinal rhodopsin<sup>10</sup>. The ester could be converted to alcohol before transfer to the retina, but it is more likely that it is transported unchanged and hydrolysed in the ROS. The latter cannot synthesise ester, although other parts of the retina can<sup>14-16</sup>. The derivative of vitamin A that is converted to 11-*cis*, and where this isomerisation takes place in the eye, is being investigated and will be discussed elsewhere.

## Corrigendum

In the article "Mutation rate, genome size and their relation to the rec concept" by J. A. Heddle and K. Athanasiou (*Nature*, **258**, 359, 1975) the following corrections should be made. Page 360, line 5: the value of *m* should be  $1.68 \times 10^{-19}$ ; line 6: the *b* and *r* values should be 0.91 and 0.98, respectively. In Table 2 the genome size of  $\phi$ X174 and  $\phi$ 13 should be  $1.7 \times 10^6$ .

## Nature Index and Binders

The **Index** for 1974 is still on sale, price £1 65. **Binders** for the journal are also available at £2.30 each, £6.25 for three (a year of *Nature* fits into three binders).

Postage is included in the above prices. Orders should be sent, accompanied by remittance, to Macmillan Journals Ltd, Brunel Road, Basingstoke, Hampshire, England.

## Chinese cosmology

GRIBBIN'S essay<sup>1</sup> is based on a few pages of Joseph Needham's *Science and Civilisation in China*<sup>2</sup>, but makes an exaggerated claim for Chinese openmindedness as contrasted with Western narrowness by disregarding Needham's sensitivity to context and implications, and by painting an extremely one-sided picture of the European tradition. The statement that Western science was a branch of religion three hundred years ago is either misinformed or extremely ill-stated. Gribbin confuses cosmology and astronomy when he talks about the centre of development of the science shifting to the West by the end of the seventeenth century. "The science" must mean astronomy, mentioned in the preceding sentence. It is impossible to sustain an argument that the centre of astronomy lay in China until that time. Needham proves that early Chinese astronomy was as estimable as that of the West, but his argument ignores the consistent superiority of Europe in computational astronomy. Gribbin is apparently unaware of the work of Nakayama<sup>3</sup>, myself<sup>4</sup>, and others who have provided independent quantitative comparisons in the nearly twenty years since volume 3 of *Science and Civilisation in China* was completed.

Gribbin's article reads like a caricature of Needham, because he ignores everything that does not fit his thesis. One could make an equally one-sided argument in the other direction by noting that Aristarchus of Samos, in the third century BC, asserted that the Earth revolves about its own axis and about the Sun, an idea that never appeared independently in China. Aristarchus also suggested that the stars were immeasurably far from the Sun, but Gribbin does not mention this.

Although it is true, as Gribbin says, that any study of Chinese astrology and cosmology must draw on Needham's work, it cannot end there. Needham's sections on astronomy and mathematics depend much more heavily on the secondary literature than his later volumes. His accounts of early cosmology require correction from other sources. The earliest concept did not, as Needham and Gribbin claim, represent the heavens as a hemispherical dome. As Nakayama has

shown in English, there were two stages; in the first sky and Earth were flat, and in the second they were indefinitely vault-shaped. The second concept was not that of "a celestial sphere surrounding the spherical Earth". Recent Chinese research has proved what Western writers have suggested, namely that the Earth in this model was either flat or hemispherical<sup>5</sup>. Neither concept, in fact, was a cosmology either in the modern sense or in the sense that gave philosophical cosmology authority over computational astronomy in the early West. The two Chinese concepts did not displace each other because it was a matter of no practical consequence which was correct. The independence of astronomy from cosmology in China has been noted by many recent writers. Of the several ancient authorities that Needham cites regarding the "empty space" theory, only one was an astronomer.

Gribbin's reading on supernovae also inadequately represents the very considerable literature that has accumulated<sup>6</sup>. He does not mention the best-documented supernova of all, that of 1006, and does not seem to be aware that Ho *et al.* have produced evidence to cast considerable doubt on his identification of the supernova of 1054 with the Crab Nebula<sup>7</sup>.

Now let me take up what I consider ill advised about Gribbin's topic itself. Historians of science have by now given up treating ancient speculations as foreshadowings, forerunners, or anticipations of the precise concepts of the modern exact sciences, since no one who has hunted for such anticipations with sufficient determination (and willingness to abide bad metaphors) has failed to track them back to the dawn of history. Instead historians think of early ideas as constituents in an endlessly complex and never predictable development from one phase of understanding and practice to the next. I am unable, in any case, to understand why Gribbin believes the Mohist idea that motion requires duration is equivalent to any innovation of Einstein. He also finds deep significance in the fact that the Chinese language includes a compound in which one character stands for space (in the everyday sense) and one stands for time, but this is a purely lexical matter, and has nothing at all to do

with the modern physical concept which we express inadequately in quotidian language as "a continuum in four dimensions".

To sum up, Dr Gribbin has not taken the trouble that he assuredly would have done had he prepared a scientific paper for *Nature*. He has not studied enough, and has not taken sufficient pains to understand what he has studied.

## Moinian and Lewisian of Sutherland and the Morarian Orogeny

IN view of speculation concerning the Moinian geology of Sutherland<sup>1,2</sup>, a short resume of our research in central Sutherland (S.J.M.) and the Bettyhill-Strathly area of north-eastern Sutherland (V.E.H.) is of interest.

In central Sutherland there are three large, sub-parallel Lewisian sheets within the Moinian west of the migmatite complex<sup>3</sup>. In the Bettyhill-Strathly area there are sheets and broad areas of Lewisian. Our extensive geochemical data indicate that the majority of the Lewisian in these areas has strong Scourian affinities<sup>4-6</sup>. The Borgie Lewisian<sup>6</sup> and that at Ribigill near Tongue (unpublished), contains both Scourian and Laxfordian types. Geochemical distinctions between the western and the eastern Moinian in northern Sutherland<sup>7</sup>, cited by Garson and Plant<sup>1</sup>, represent a distinction between Moinian with extensive basic Lewisian in the west, the Tongue-Borgie area, and acid Lewisian with

some Moinian in the east, the Armadale-Strathly area.

Garson and Plant<sup>1</sup> and Johnson<sup>2</sup> mention ultrabasic bodies intruding the Moinian and the Lewisian of Sutherland, as originally described by Read<sup>3</sup>. Our detailed field mapping has shown them to be restricted to the Lewisian. Read<sup>3</sup> and the later authors<sup>1,2</sup> apparently confuse a series of Lewisian metaperidotites and garnet pyroxene rocks (garnet pyroclastics) with early Moinian metabasic intrusives. Geochemical and petrological evidence indicates that the garnet pyroxene rocks of the Naver and Borgie<sup>4</sup> Lewisian are identical to those of the foreland Lewisian<sup>9,10</sup>. Similarly, the metaperidotites are identical to analogous rocks found throughout the foreland Lewisian<sup>8,10,11</sup>. These bodies are not, therefore, synchronous with the emplacement of the Lewisian sheets (see ref. 2), they are an integral part of them. Neither are they high level diapirs (see ref. 2); nor do they constitute a Moinian ophiolite zone (see ref. 1).

Several authors have speculated an extension of the Sgurr Beag Slide<sup>12</sup> into central Sutherland<sup>2,13,14</sup>. Although slides are present there is no definite evidence that any are continuous with the Sgurr Beag Slide. The Lewisian sheets of central Sutherland seem to have been emplaced by a combination of early (F1) isoclinal folding and possible sliding, which has been modified by later (F2) folding and sliding. The continuation of the Sgurr Beag Slide may, however, occur in north-eastern Sutherland, thus extending Johnson's speculation<sup>2</sup>, the Lewisian of central and northern Sutherland may be the root zone of Moravian nappes represented by the large areas of Lewisian in north-eastern Sutherland.

## Evolutionary changes in insulin

BLUNDELL and Wood<sup>1</sup> propose "a model for the evolution of insulin mainly in terms of adaptive processes". Simultaneously they raise questions regarding "conclusions made on the basis of uniform rates and changes that seem not to affect function", such conclusions being attributed to Kimura<sup>2</sup> and to King and Jukes<sup>3</sup>. They do not mention the more recent discussion by Kimura and Ohta<sup>4</sup>, who point out that insulin in general has a very low evolutionary rate, corresponding to a strong negative-selection barrier. Blundell and Wood's model calls for functional restraints on most of the amino acid residues. Kimura and Ohta also noted that the C peptide of proinsulin evolves about 10 times as fast as insulin, and is therefore a much better candidate for neutral mutations than insulin itself. and they proposed that the absence of zinc from guinea pig insulin results in a loss of constraint on the fixation of mutations.

## Specificity of transfer factor

In an article on the use of transfer factor (TF) in treatment of viral infections<sup>1</sup>, Zuckerman states that "clinically, TF activates uncommitted and non-sensitized lymphocytes of the recipient so that new clones of antigen-specific cells are produced". He goes on to make the point that the delayed-type skin reactivities that are transferred after injection of TF are those possessed by the donor. It is undoubtedly true that the results obtained during the past 25 yr by Lawrence and others are most readily explained by the existence of such specificity<sup>2</sup>. The problem is, however, that nobody has found a way in which specificity can be demonstrated in unequivocal terms and by procedures which allow for confirmation in other laboratories. At the recent Second International Workshop on Basic Properties and Clinical Applications of Transfer Factor at Fort Detrick, there were more than 100 participants and not one convincing demonstration of specificity.

Failure to convince does not disprove the concept of antigen specificity, but it is worrying. It may be due to the difficulties of human experimentation and the lack of a satisfactory animal

model. One possibility is that TF preparations contain both a specific factor and nonspecific adjuvant-like factors, and that this is creating problems in man where the antigens normally studied are not complete strangers to the 'negative' donors and recipients. The various *in vitro* systems that have been used have not pointed to specificity, although there is no guarantee that the factors active *in vivo* are being assayed. The work of one of us has involved the action of human TF on macrophage migration and lymphocyte transformation<sup>3,4</sup>. Evidence obtained in the latter system suggests that the action of TF is nonspecific but that the level of this nonspecific activity is greater in tuberculin-positive than in negative individuals.

Doubts about specificity are especially relevant in the clinical field where there is clear evidence that TF can boost phytohaemagglutinin responsiveness and the number of cells forming rosettes with sheep erythrocytes<sup>5,6</sup>. This nonspecific action could be responsible for the appearance of delayed hypersensitivity and clinical improvement.

## Insectivorous grouse?

BEFORE embarking on the "full-scale investigation of the relationship between grouse and insects" recommended by your Animal Ecology Correspondent<sup>1</sup>, the cautious research worker might wish to establish that incubating hen red grouse do in fact eat many tipulids. This is crucial to the suggestion that hen grouse on wet moors may rely on tipulids to redress their supposed state of 'nutrient depletion' after egg laying. The work by Butterfield and Coulson<sup>2</sup> did not show that adult hen grouse eat tipulids at this stage, although it would not be surprising if readers of their paper were to infer that they do.

Although Butterfield and Coulson present data for the month of May, when hens are incubating, the dropings that they collected in May were from cock grouse. How do we know this? When incubating, hen grouse

produce large, distinctive 'clocker' droppings, rather like those of broody chickens. Before their paper was submitted, we asked Dr Coulson if clocker droppings had been included in the May sample, and we also described what they look like. He said they had noticed some droppings like that, but discarded them as they did not know what the droppings were.

If tipulids do 'play a vital part in the maintenance of grouse populations', as suggested by your Animal Ecology Correspondent we should expect wet, blanket-bog grouse moors where there are many tipulids to support more grouse than drier moors. In fact, the reverse is the case. The wettest moors have the fewest grouse. Contrast western Ireland where the extensive, wet bogland supports good populations of tipulids (A. N. Lance, personal communication) but very few grouse<sup>3</sup> with the typically dry moors in the north-east of Scotland where grouse are abundant<sup>4</sup>. Almost all good grouse moors are on dry ground and the association between dry ground and good grouse shooting is so widely understood that draining wet ground to increase grouse numbers is an accepted management practice.

The reason for this is clear. Heather covers a greater proportion of the ground and grows best on dry moors, and numbers of grouse are correlated both with the proportion of ground covered by heather and with the vigour of its growth<sup>5</sup>.

The nutritional requirements of an adult grouse are highest when the hen is laying eggs. It is this time when nutrients are most likely to be limiting and when insect food is most likely to be an important dietary supplement. Laying hen grouse do not eat many insects, because insects are not abundant this early in the season. The suggestion remains that hens become depleted of nutrients while laying eggs and that insect food, especially tipulids, is essential during the incubation period in order to redress this hypothetical imbalance. It is not claimed that this occurs on dry moors, because adult grouse eat few insects on dry moors. The suggestion is limited to wet moors.

This limitation implies that there must be some difference between the diets of laying hens on wet and dry moors, such that hens on wet moors are less well fed than on dry moors. This is possible because one important determinant of the hens' plane of nutrition in spring is the density of heather available<sup>6</sup>; and heather tends to be sparser on wet moors<sup>7</sup>. Therefore we agree that it would be wise to improve the hens' plane of nutrition in spring.

It is most helpful to improve the

food for the hens before they begin to lay eggs. When the laying hens' food is good, the chicks which hatch survive better<sup>8</sup> as a result of improvement in the quality of the eggs<sup>9</sup>. The food can be improved by proper heather management, which includes draining on wet moors and results in the provision of a dense array of heather shoots. The alternative suggestion, mooted by your Animal Ecology Correspondent, is that tipulids should be provided after the hen has laid her eggs. This procedure can have no effect on the quality of the eggs.

There is no evidence that hen grouse do eat tipulids during incubation. Even if they do, there is no evidence that tipulids are ever in short supply on wet moors. The only observed association between tipulid densities and grouse numbers is that grouse stocks are higher where there are fewer tipulids—on dry moors.

We do not attempt to argue that tipulids are totally unimportant on wet moors, because there is no direct evidence one way or the other. But we do suggest that heather will remain much more important for grouse numbers than tipulids, even if the 'nutrient depletion' hypothesis proves correct.

## Temperature, phenoxybenzamine and adrenoceptor transformation

In his letter<sup>1</sup> Benfey suggests that the adrenoceptor transformation hypothesis is incorrect because temperature-induced changes in the block by and binding of phenoxybenzamine (POB) in frog hearts<sup>2</sup> could result from a change in the rate of alkylation of nonspecific nucleophilic centres. The impression is given that the hypothesis is based only on the observed effects of POB, however, several reports indicate that the competitive  $\alpha$ -adrenoceptor antagonist, phentolamine, can also effectively inhibit inotropic and chronotropic responses to catecholamines in the hearts of various species at low temperature<sup>3-7</sup>. In addition, tem-

perature is not the only factor that has been shown to alter the properties of adrenoceptors. Cardiac inotropic and chronotropic responses in hypothyroid rats are affected by POB and phentolamine at high temperatures similarly to those of normal hearts at low temperatures<sup>8-10</sup>. These observations clearly cannot be due to an effect of temperature on nonspecific alkylation. A nonspecific temperature effect might explain Benfey's observation<sup>1</sup> that POB blocks acetylcholine more effectively at higher temperatures. This temperature effect, however, is opposite to that observed with cardiac adrenoceptors, and parallels the increase in POB binding we have found in homogenised myocardium. Protection from POB block by high concentrations of membrane stabilisers does not prove that  $\alpha$ -adrenoceptors are not involved. Local anaesthetics can influence the apparent affinity of an antagonist with  $\alpha$ -adrenoceptors<sup>11</sup>.

The concentration of POB required to block responses to adrenaline in frog hearts at low temperature is clearly higher than that required to block  $\alpha$ -adrenoceptors in vascular smooth muscle, however,  $\alpha$ -adrenoceptors are probably not all identical. Relatively high (micromolar) concentrations of either POB or phentolamine are necessary to inhibit presynaptic  $\alpha$ -receptors in the heart<sup>12,13</sup> and all but one study demonstrating an  $\alpha$ -adrenoceptor component of inotropic responses of mammalian hearts have used high concentrations of  $\alpha$ -blocking drugs<sup>8,10,14-17</sup>. The only claim that nanomolar concentrations of POB or phentolamine can inhibit responses to phenylephrine in rabbit left atria<sup>18</sup> is disputed<sup>19</sup>. Lack of complete block with even high concentrations of  $\alpha$ -adrenoceptor antagonists could also reflect the fact that no 'pure' cardiac  $\alpha$ -adrenoceptor agonist is available, and the considerable residual  $\beta$  activity at low temperature, or in hypothyroidism, could 'mask'  $\alpha$ -adrenoceptor block.

The absence of a temperature-induced difference in the blocking action of propranolol or in the relative potencies of agonists reported by Benfey is contrary to observations from several laboratories<sup>3-7</sup>, and the reason for the difference is not clear. His data do, however, suggest that propranolol is more effective in hearts that are more responsive to  $\beta$ -adrenoceptor stimulation. The standard errors in his Table 1 indicate up to 50-fold variation in sensitivity to isoproterenol. Propranolol greatly reduced this variability, showing a greater effect on the more sensitive preparations. Benfey does not indicate the temperature during exposure to propranolol: incubation at 24 °C before testing the block at 14 °C could account for the lack of a decrease in inhibition

It is unlikely that the previously reported effect of propranolol at low temperature<sup>3-7</sup> was due to inadequate diffusion of the drug. Benfey found that atropine produced the same block at low and high temperatures after 10-min incubation. Hypothyroidism also reduced the inhibitory effect of propranolol, although all tests were at the same temperature and after 30-40-min incubation<sup>8-10</sup>.

In conclusion, Benfey's data seem to be inadequate to support his contention that the hypothesis of adrenoceptor transformation is an artefact attributable to nonspecific alkylation by POB

**BENFEY REPLIES**—The above comment<sup>1</sup> on my letter<sup>2</sup> misses the point. The real issue is not whether a change of temperature alters the rate of alkylation by phenoxybenzamine (although it obviously does), it is not how much phenoxybenzamine is required to block  $\alpha$ -adrenoceptors (although Kunos *et al.*<sup>3</sup> loaded the tissue by four 10-min exposures to 2.5  $\mu$ g ml<sup>-1</sup> of the highly lipid-soluble drug), and it has nothing to do with hypothyroid rats (although it may be noted that mammals have cardiac  $\alpha$ -adrenoceptors in normal conditions at normal temperature<sup>4</sup>). The issue is whether lowering temperature transforms the adrenoceptor of the frog heart from its characteristic  $\beta$ -type into an  $\alpha$ -receptor. If this were so, one might reasonably expect that phenylephrine would be more potent at a low than at a high temperature,

that the reverse would be true for isoprenaline, and that the blocking ability of propranolol might be changed by lowering temperature. These predictions were not supported by my experiments, and this was the reason for not accepting the hypothesis that the nature of the adrenoceptor changes with temperature<sup>2</sup>.

## *Aedes aegypti* complex in Africa

We wish to discuss aspects of the communication by Scott and McClelland<sup>1</sup>. It was pointed out long ago that sound ecological studies depend on the accurate determination of the evolutionary status of the organisms under study<sup>2</sup>. This is especially crucial in applied biology<sup>3</sup>. If two forms are common and sympatric there are three possible situations. (1) They are reproductively isolated and do not exchange genes under natural conditions; in other words they are distinct species. If they are not reproductively isolated (that is they mate with each other in nature), they may represent (2) two subspecies (races) whose ranges have recently intersected to form a transient area of sympatry where hybridisation occurs, or (3) morphs of a single polymorphic species<sup>4</sup>. The concepts behind these possibilities are well established and backed by sound bodies of theory, and many studied examples of each are documented<sup>5</sup>.

Scott and McClelland dealt with the sympatric occurrence of the dark and pale forms of the current taxon *Aedes aegypti* L., a mosquito of considerable medical importance. The pale form has a wide distribution within and beyond Africa, and is domestic in its habits. The dark form is confined to Africa south of the Sahara, and is an outdoor mosquito<sup>6</sup>. These facts and the data on the alkaline phosphatase and protein loci provided in Table 1, of ref. 1, are sufficient to eliminate the possibility that we are dealing with a single polymorphic species. In fact, the data for these two loci provide strong evidence for the existence of positive assortative mating in the field, thus supporting the view that they are distinct genetic species. It should be emphasised that the evidence for random mating in cages and for the interfertility of the two forms is of little relevance in assessing the status of the forms because it is well established that distinct genetic species are often interfertile

in artificial crosses<sup>7,8</sup>, and cases are known where distinct species mate at random in cages<sup>7,9</sup> but positively assortatively in nature<sup>7,10,11</sup>.

We think that it is unfortunate that Scott and McClelland used the vague and imprecise terms "ecotype" and "incipient species". "Ecotype" is a term introduced for plants and is not appropriate to animals. The term "incipient species" is not appropriate here, as it is usually used in narration to imply some well marked subspecific stage. Neither term is backed by a satisfactory body of theory. The opening sentence of the report immediately leads to confusion by implying that "ecotypes" are not populations.

**SCOTT AND MCCLELLAND REPLY**—We agree that the status of the two entities is crucial to the paper. We believe that field hybridisation has been amply demonstrated (refs 4 and 9 of our report in *Nature*<sup>1</sup>). A computer simulation of this situation containing three genotypes, three habitats, two seasons, parameters for rate of movement, habitat selection, natural selection and assortative mating, is now under review. It demonstrates that polymorphism is highly probable, provided only that: (1) there is a dry season when breeding occurs only in the indoor habitat; (2) fitness of the indoor ecotype is greater in houses, and fitness of the outdoor ecotype is greater in the natural habitat; and (3) movement between indoor and outdoor habitats is not large (less than about 25% of the indoor inhabitants must be immigrants each generation). The computer model shows that, when mating is random, polymorphism is probable.

## Bull's-eye of sociality

THIS is a book\* addressed to a wide audience and one likely to make a lasting impact on biological thought, research and teaching. Its title puts a new name to a subject that is among the fastest-growing areas of biology, and its contents do indeed provide a new synthesis, of wide perspective and great authority.

Dr E. O. Wilson is one of the best-known zoologists of the day, and collaborated with the late Robert MacArthur in writing the biological best-seller, *Island Biogeography* (1967). Since then he has produced, among other works, a large, universally acclaimed monograph on *The Insect Societies* (1971). His output is extraordinary: *Sociobiology* itself contains about half a million words. His plain uncluttered prose is a treat to read, his logic is rigorous, his arguments (even the occasional mathematics) are lucid. He is a real polymath, threading a constructive path through forests of zoological literature and, as far as one can tell, rarely putting a foot wrong. In a difficult and controversial field, his deductions are informed, balanced and fair, even though some are necessarily questionable.

The book is an evolutionary study of social biology throughout the animal world, or more exactly, throughout the Metazoa. It is divided into three sections of which the first, 'Social Evolution' is the shortest, and deals among other subjects with the fundamentals of sociality, population biology, and selection processes. The second, *Social Mechanisms*, covers communication, dominance and territorial systems, parental care, and much else. The third is entitled *The Social Species*, and in 200 pages provides a critical review of more than 30 selected groups, chosen from the invertebrates, cold-blooded vertebrates, birds, mammals and primates (including man). The coverage and digestion of the literature are amazing: about 2,500 references are listed, making the bibliography a goldmine in its own right. At £11 the book is a bargain.

\**Sociobiology: The New Synthesis* By Edward O. Wilson. Pp. 697 (Belknap Press of Harvard University: Cambridge, Massachusetts, 1975.) £11.

I am no stranger to the perplexities of sociobiology; they have occupied much of my time for over 20 years. Having read the book through I find myself wondering how close Professor Wilson has come to the bull's-eye, in pondering what sociality is and does, as an evolutionary adaptation. The basic target is not easily perceived, perhaps because the adaptive value of sociality is different, at least superficially, for different animals. The simple definition he gives of a society (p7) is "a group of individuals belonging to the same species and organised in a cooperative manner". He stresses (p379), as being among the key properties of social existence, cohesiveness, altruism and cooperativeness, and often, especially in reviewing the social species, he contrasts social with solitary animals, as if flocking or sociability were also a key property. Thus he affirms (p484) that sociality has been advanced in those African mammals that have forsaken the closed forests and become adapted to open grasslands. But we know that there are many kinds of fish, birds and mammals that vary their flocking strategy from day to day and hour to hour, sometimes in fact depending on whether they are in open or closed habitats. Can the distinction between clumped and solitary dispersion indeed be fundamental?

He sees four pinnacles of social evolution, found in (1) the colonial invertebrates, (2) the social insects, (3) the vertebrates and (4) man himself, and he observes that the first three

have been scaled many times by independently evolving lines of animals, although man has scaled his peak on his own. In the context of Professor Wilson's special group, the social insects, he picks out as their particular social traits, the cooperation of individuals in the care of the young, the presence of more or less sterile individuals working on behalf of fecund nestmates, and an overlap of at least two generations capable of contributing to colony labour.

It is perhaps here that he comes nearest to identifying two other properties that seem to me to lie still closer to the bull's-eye of sociality: first, the potential endurance of animal societies, so that they characteristically outlive their current members; and second, their property of imposing duties and restraints on their members, serving to promote the common good, often in the longer term. Selection for altruism itself is admirably discussed.

He regards those animals, the colonial invertebrates, that have scaled the first pinnacle as coming close to producing perfect societies; and, looking towards the other three pinnacles, he asks why the overall trend has been downward from this primitive or simple perfection. The siphonophores are to him "the *ne plus ultra*"; whereas from my different point of view it is hard to concede that they qualify as societies at all. They are of course composite or compound animals, made up of variously modified polyps, and they use budding as a means of growth and organ differentiation; but each siphono-

phore complex develops from a single zygote into a ciliated larva, and later into a primordial polyp, forming, as it grows, a stem from which the other polyps branch. After a reproductive period its planktonic existence ends, and it dies as an entity. Perhaps it is not in every sense one individual; but can its state of organisation properly be equated with that of the higher societies on any of the other pinnacles—societies composed of separate, potentially competing, genetically different, sentient individuals, bonded together by sensory recognition and appetite, constrained by conventions

and by traditions handed down from forbears to descendants as the generations pass. Once more I must doubt it, and whether indeed the author could claim (which of course he does not) yet to have found the keys to this black box.

Ultimately these questions are important, but for the present I think they will worry most readers not at all, nor detract from the pleasure and profit to be found in this remarkable book. They do nothing to diminish its new horizons, but remind us only that we are not at the end of the road.

V. C. Wynne-Edwards

## Superconductivity

*The Superconducting State.* (Graduate Student Series in Physics.) By A. D. C. Grassie. Pp. vii+135. (For Sussex University Press; Chatto and Windus: London, September 1975.) £8.00.

THE author, in his preface, excuses the appearance of yet another book on superconductivity by claiming that "It corresponds to the level of the experimental physicist who needs to follow theoretical papers in order to analyse his results adequately . . ." Having on many occasions suffered restrictions imposed by a lack of theoretical understanding, I approached this volume with eager anticipation. It is with regret that I report that after reading, and indeed re-reading, the book my hopes remain unfulfilled.

The first chapter, an introduction to the phenomena of superconductivity, sets the historical perspective. The second, dealing with the microscopic Bardeen, Cooper and Schrieffer (BCS) theory of superconductivity requires fairly advanced quantum mechanics, and will severely tax most experimental physicists. A less mathematical treatment of BCS is probably not possible, but a closer attempt to relate formulae to physical reality would be helpful. The strong-coupling extension of BCS, which is needed to discuss the technically interesting, high critical temperature superconductors, is dismissed in two paragraphs. The limitations of the theory, for example in its ability to predict new superconductors, are ignored.

The following two chapters cover the Ginsburg-Landau phenomenological theory, and the magnetic state of type II superconductors. The treatment is on a par with those to be found elsewhere, and offers no new insight. The latter section is incomplete in that it ignores the temperature dependence of  $\kappa$ .

The reader is entitled to expect more technological bias from chapter 5, en-

titled "The Current-Carrying Capacity of type II Superconductors". The main reason for using superconductors in large electrical devices is their ability to sustain very high current densities, but the pinning of flux lines, which is directly responsible for the magnitude of the critical current, receives one paragraph. It is true that "the origin of pinning forces is still a subject of detailed research", but then so are many of the other phenomena described. There is sufficient agreement among workers interested in flux-pinning for the author to have given some indication of the physical nature of pinning forces. The discussion of flux instabilities is better, though in one of the all too rare numerical calculations the author arrives at the incorrect value of 0.042 cm for the critical half-thickness of a stable conductor. Using the author's formulae and quoted values for parameters, the correct answer should be 0.003 cm, a value which looks less out of place with the accompanying photograph of a multifilamentary conductor.

The final chapter is concerned with Josephson effects, and the devices which use them. This is the best chapter in the book, not only because it is the most original. But at six pence a page, the book must be regarded as expensive.

David Dew-Hughes

## Insect biochemistry

*Insect Biochemistry and Function.* Edited by D. J. Candy and B. A. Kilby. Pp. xii+314. (Chapman and Hall: London, May 1975. Distributed in USA by Halsted Press.) £8.50.

THOSE expecting a comprehensive textbook of insect biochemistry will be disappointed. This book is in fact a collection of four review essays describing the biochemistry of certain functions in detail, and the authors assume the reader to have a good basic knowledge of biochemistry. The

greater part of the book is devoted to aspects of insect flight, with one chapter on the utilisation, and another on the sources of fuels for flight. The first describes the metabolic pathways for the release of energy from carbohydrates, fats and amino acids. Emphasis is placed on the complex interactions resulting in the breakdown of muscle glycogen as an immediate source of energy, the importance of certain metabolites (especially  $\alpha$ -glycerol phosphate, proline and acetyl carnitine) for penetrating mitochondria, and the mechanisms responsible for controlling mitochondrial metabolism, which may increase by as much as 100 fold on the initiation of flight. The nature of these fuels for flight, and the sites for their storage are described belatedly in the second chapter. The importance of the various energy sources for both short and long periods of flight are discussed, and attention is drawn to the central role of the fat body in synthesising and storing these fuels.

The diversity and origins of excretory materials produced by insects is the subject of the third essay which dispels the firmly entrenched generalisation that insects are primarily uric acid excreting organisms. Many nitrogenous compounds are excreted, including ammonia which, despite its great toxicity, is now recognised as a major excretory product in some terrestrial insects. The accumulation of uric acid within the insect body has until recently been thought of as excretion, but evidence is reviewed that this metabolite is mobilised in times of dietary stress, possibly by intracellular symbionts within the fat body.

The final contribution is a concise assessment of our current knowledge of synaptic transmission in insects. After a general outline of the structure of the insect nervous system, cholinergic transmission is summarised very briefly, and the remainder of the chapter is devoted to a discussion of the evidence for glutamic acid,  $\gamma$ -amino butyric acid and biogenic amines as excitatory and inhibitory transmitters both peripherally and in the central nervous system.

Although the editors draw attention to the importance of comparative aspects of biochemistry in achieving selective toxicity in chemicals used for pest control, little emphasis is placed on these, even in the most relevant chapter on synaptic transmission. The book provides, however, good reviews of the three topics, and these have comprehensive bibliographies (the chapter on excretion being especially notable in this respect). It should prove useful reading for both undergraduates and research workers in insect biochemistry. A. L. Devonshire

## Tool not a discipline

*Enzyme Kinetics: Behaviour and Analysis of Rapid Equilibrium and Steady-State Enzyme Systems.* By Irwin H. Segal. Pp xxii+957. (Wiley-Interscience: New York and London, July 1975.) £15.00.

ONE might have expected a book on enzyme kinetics by I. H. Segal to make as useful a contribution to its field as his *Biochemical Calculations* has made within its own category of elementary textbooks. Unfortunately, this has proved otherwise. His new volume is a long and detailed account of just one aspect of enzyme kinetics: steady state methods. Yet it is possible to read through its excess of 900 pages and at the end of it not to have learnt anything about the behaviour of enzymes. The rationale of the study of the kinetics of enzyme reactions is surely the information that kinetic methods provide about the operation of enzymes, either from the viewpoint of the elucidation of the chemical mechanism of the enzyme or the understanding of some biological phenomena. In my opinion, enzyme kinetics is a tool of biochemical research, not an intellectual discipline within its own right. This book presents the latter view.

The heart of the book is a catalogue of steady-state rate equations for enzyme mechanism containing one, two or three substrates reacting with the enzyme in all possible sequences together with the inhibition patterns expected for different types of inhibitors. The mathematics have been presented clearly and double-reciprocal plots of reaction velocity against reactant concentration illustrate most of the equations. No examples of the use of these equations in enzymology are given, which is regrettable because the value of a method can only be judged by the problems it solves. The nomenclature of enzyme mechanisms used throughout the book is that of Cleland. But the principles of steady state kinetics were established more than 20 years ago by Haldane, Alberty and Dalziel, who demonstrated when these methods could distinguish between alternative reaction mechanisms and, equally important when they could not. The newer nomenclature of Cleland is useful on account of its systematic approach but yields no new principles nor unifying concepts. The same comment might apply to this book. The effort here has been expended on description rather than comprehension. For instance, it has never seemed to me helpful to use terms such as Bi Uni Uni Ping Pong Ter Bi to denote a reaction mechanism since they fail to advance an understanding of the mechanism at the physical level.

Therefore, this book is recommended only to professionals working in the field of steady state enzyme kinetics. Though the derivation of the rate equations for any single mechanism is tedious rather than difficult, some will find it useful to have available a compendium of steady state equations for a variety of different systems derived for them. But the restriction to a single experimental method treated in a purely theoretical manner renders the book unsuitable for the general student of biochemistry. One can admire the rigour with which the author approaches his subject but not the basic premise from which he starts.

S. E. Halford

## Breath of air

*Principles of Comparative Respiratory Physiology.* By Pierre Dejours. Pp. xvi+253. (North Holland: Amsterdam and Oxford; American Elsevier: New York, 1975.) Dfl. 35; \$14.75.

HAVING an almost exclusively neurophysiological interest in respiratory movements, I undertook the reviewing of *Principles of Respiratory Physiology* with some trepidation, since I knew this would force me to tread very unfamiliar paths through the jungle of work on respiratory gas exchange in different animals. I am glad to say that my fears were unfounded. True Frenchman that he is, Dr Dejours has created a masterful 'Guide Bleu' through this jungle, providing a clear trail for the timorous, yet offering the more adventuresome rich local detail and source references on which to linger.

I particularly like the way in which he deals with the relevant physical principles of diffusional and convective gas flows, the  $O_2$  and  $CO_2$  capacitances of the gaseous and fluid compartments of the respiratory system and their corresponding  $O_2$  and  $CO_2$  conductances. The operation of these principles in the living organism is illustrated throughout the book by appropriate reference to phylogenetic or species specific mechanisms of gas exchange in both water and air breathers representing the most lowly and most complex of animals. The net result of this endeavour is that Dejours has produced an impressive, overall view of gas exchange even for the most complex Metazoa in which he traces the flow of  $O_2$  from the environment to the mitochondrion by way of the alveolar gas, gas-blood barrier, blood, systemic capillary walls, interstitial fluids and cell membrane, together with the flow of  $CO_2$  in the reverse direction.

The clear authority of the author is no better marked than in the closing chapter where he expresses the view point that the principal aim in the

control of respiration is the adequate oxygenation of the tissues in contrast to the more commonly held view that it is the  $CO_2$  pressure and acid-base balance which are primarily regulated. His defence rests on the evidence that only long term changes in the needs of oxygenation lead to significant adaptive morphological, biochemical and physiological changes of the organism.

Highly recommended to all air breathers interested in respiration.

T. A. Sears

## Electronic structure

*Electron Densities in Molecules and Molecular Orbitals.* (Physical Chemistry: Series of Monographs, Volume 35.) By John R. Van Wazer and Ilyas Absar. Pp ix+101. (Academic: New York and London, September 1975.) \$14.50; £7.25.

THIS is an unusual book. Essentially the authors have a computer programme for Hartree Fock electronic wave function calculations for molecules incorporating flexible possibilities for the basis sets and a perspective three-dimensional graphic output expressing the electron density throughout a cross-sectional plane. This they use for total and for one-electron densities for  $LiF$ ,  $H_2O$ ,  $HCP$ ,  $C_2H_6$ ,  $PF_3O$  and some 30 other molecules. The book largely presents these graphics and associate text for undergraduate chemists "whose minds are spatially oriented"; for the more expert there is little except possible illustrations for a lecture.

A greater attention to detail is necessary, such as clear bold labelling of the molecule for each figure, clear indications of the nuclear positions, clearer depiction of nodal lines, omission of slapdash jargon—such as reference to the  $C_3$  axis of  $PHF_2O$ —and careful spatial orientation of all figures relating to the same molecule such as 3.1 and 3.2 on page 29. Emphasis on the shape of the electron density in a single cross section downgrades the importance of kinetic energy, ignores spin effects, ignores time correlation features associated with configuration interaction and leaves the weaker student with a dominant picture of molecular orbitals as sharp peaks on each nucleus (where  $\psi^2$  remains large for s orbitals) surrounded by a trough (associated with the relatively unimportant spherical nodal surface in 2 s orbitals) and a few small bumps associated with bonds.

Others may agree that there are better ways of introducing simple electronic structure to undergraduates.

D. H. Whiffen

# obituary

**Professor Thomas A. Bennet-Clark**, CBE, FRS died peacefully after a long illness on November 24, 1975. He was born in Edinburgh in 1903 and educated at Marlborough College and Trinity College, Cambridge, where, under the inspiration of F. F. Blackman, he switched from Chemistry to Botany, and won the Frank Smart prize (1923). He started research under Blackman but after a year moved to Trinity College, Dublin, to become research assistant to H. H. Dixon. From 1930 to his retirement in 1967, he held University posts in Manchester, Nottingham, Kings College, London and East Anglia.

Blackman's influence on Bennet-Clark can be seen in his early contribution to plant metabolism, but he went beyond the essentially analytical work of Blackman. Whereas Blackman's analysis of the Pasteur effect in apples made no reference to foreign research, Bennet-Clark was quick to recognise the deep significance of Meyerhof's work on muscles. Bennet-Clark's work on metabolism was a landmark and initiated a series of investigations leading from those of Meirion Thomas on CO<sub>2</sub> fixation to the present recognition of the underlying biochemical unity in the organic acid metabolism of succulents and C<sub>4</sub> plants.

The six years spent with Dixon were particularly happy years. The work at Dublin on cell membranes and permeability led to a study of osmotic relations. This work raised the possibility of the active uptake of water, which excited much interest and inspired a great deal of experimentation in plant biophysics.

Bennet-Clark adapted filter paper chromatography for the assay of activators and inhibitors of plant growth. This work initiated an important series of investigations on plant hormones particularly involving the work of Wain and Wareing. His work on diageotropism (in collaboration with Sir Nigel Ball) did not lead to major developments in plant physiology. The experiments do, however, reveal great ingenuity and originality, and should be read by all young plant physiologists.

Bennet-Clark's contribution to Plant Physiology was highly original but its quantity was not large. Partly this was due to his high regard for quality, partly due to limited facilities, but most of all due to his unselfishness. He was full of ideas, his quick mind produced lateral thoughts at an alarming rate, few, however, were tested experimentally because he would not use his great influence in the ARC and in other quarters to fund his personal researches. This was undoubtedly a

mistake, but given Bennet-Clark's character, it was inevitable.

He was a gentle, kind man with a wry sense of humour and a charming eccentricity which endeared him to the hearts of his students and colleagues. He always found time to help those in difficulty and his advice on both scientific and personal matters was appreciated by many. He was an outstanding teacher and lecturer. He liked to pretend that he knew little taxonomy, but his encyclopaedic mind contained a stock of information on taxonomy and many other topics which were subject to instant recall and association in novel ways.

Bennet-Clark contributed greatly to the success of the Society for Experimental Biology and the Journal of Experimental Botany, of which he was the first editor. His scientific achievements were recognised by his election to the Royal Society in 1950 and his work for the Agricultural Research Council was recognised by the award of a C.B.E. The association of the Food Research Institute and the John Innes Institute with the University of East Anglia is a monument to Bennet-Clark. But his colleagues will remember above all his great personal qualities. We loved him and mourn his passing.

D. Davies

## Have you ever thought of going into industry?

DOES Britain do enough to ensure that the merits of industry as a career are presented to young people?

In the last year the feeble productivity performance of British industry has been brought to public attention with depressing frequency. The figures speak for themselves: in five years the productivity index has risen by only 13%, the index of actual production by less than 2%. As we have noted before, the academic world has been weighing in recently with its own remedies, generally aimed at improving the rather bad university/industry links at the postgraduate end of the spectrum. Raising the productive capacity of industry has also been the recent theme of Mr Fred Mulley, Secretary of State for Education and Science, who has been urging students to think more of industrial careers and less of academe or the civil service.

There are, of course, two fairly distinct routes by which graduates get into industry. One is by making a definite choice around the age of seventeen to pursue engineering at university. The other is by pursuing some other course at university which does not exclude the possibility of working in industry. But it is by no means obvious that the student of seventeen will have enough information available to him or herself to make a reasoned judgement on whether to go into engineering.

Ask any schoolteacher what causes a child to opt for engineering and the most likely answer is that family influences play a major part. Parents or uncles who are themselves engineers seem to be the examples which lead many young people into the profession themselves. In this respect, engineering runs parallel to farming and medicine. The next most common reason for going into engineering is the conspicuous presence of a potential employer, probably in the local town—though three years later the graduate may well have a different opinion about returning home, of course.

Both of these reasons are rather good ones with a high content of realism in them, but what of the student without engineering in the family and with no particular employment in mind? The claims of engineering are, in general, rather poorly represented to him or her. Quite rightly there is a strong insistence in schools on the pur-

suit of mathematics, physics and chemistry, so few engineers are to be found amongst schoolteachers. Small wonder, then, that many pupils will have never seriously considered engineering as an option to be set against a 'science' course at university.

Obviously those who do choose to do science have a chance to enter industry in a variety of ways upon graduating. But their period at university is likely to be one in which they will hear that pay in industry is not as good as it could be, because industry does not prize its graduates. They will also hear that the prospects of a science-trained employee getting to the boardroom are decidedly inferior to those of, say, an accountant. And even if these statements are not universally true, few in the university science environment are in a position to, nor sometimes wish to, speak in defence of industry.

There are many ways in which the recruitment of scientists for industry and the recruitment of students into engineering deserve attention, but the greatest advance surely awaits the removal of the barriers which in most universities separate engineering students from science students. In many cases hardly a course is taken in common even though the subject matter, particularly in mathematics and physics, runs broadly parallel. If a physics department wishes to teach electronics it will call on a physicist to do so; if an electrical engineering department needs a course in solid state physics it will be taught by an electrical engineer. These tendencies are greatest in the older established universities. The result is often inferior teaching, and, worse, the erection of disciplinary barriers by students themselves.

In recent months there has been some fairly radical talk about the need for postgraduate training modelled on the (best) American institutions. These same institutions are offering undergraduates a diversity which is unmatched in Britain and which allows the student to delay the difficult specialisation decision as long as possible. Critics claim that this leads to academically lightweight graduates: it does on the other hand lead to a greater maturity in making decisions about careers. And who can say that in the United States industry has not profited from the flow of excellent graduates? □

**Paul Richards**, coordinator of research for the International African Institute's Environmental Review Unit, examines new approaches to environmental research and explains

## What environmental crisis means in Africa

**E**NVIRONMENTAL crisis has become a major neurosis of the seventies, and monitoring and resource management two of its most commonly advocated therapies. But these therapies mean different things in different parts of the world. For richer industrial countries the focus is on the conservation of fossil fuel resources and on pollution problems. But in poorer regions securing the year's food supply from an increasingly overstretched agricultural system frequently overwhelms all other considerations. Atmospheric pollution and petrol rationing are minor irritations in a context of underdevelopment so severe that up to 50% of all live-born children die before they reach the age of five. For the poorest countries, therefore, dead fish and factory-poisoned rivers might be considered welcome evidence of a turn for the better and a small price to pay for escape to prosperity. In contexts such as these, environmental monitoring will tend to focus on nutritional rather than pollution levels, and resource management must, almost of necessity, emphasise quick exploitation rather than longer term conservation.

The distinction between richer and poorer countries in environmental matters goes much deeper than the mere exigencies of current economic planning, however. Environmental research is often location specific, and poorer regions have had less than their fair share of attention in this respect. This in itself is a factor making for continued poverty. Tropical climatology, for example, is a much less well-researched and closely monitored field than its temperate latitude equivalent, with the result that recent drought in Africa has been much less easy to foresee and its consequences much less easy to plan for. But by far and away the most important distinction is that, by taking part in the world trading system, richer nations have been able to diversify and build flexibility into their economies while poorer nations have found themselves beset by a process of structural simplification rendering them less able to withstand environmental shock. Thus the export crop plantation and pesticide spray replace the ecologically subtle polyculture of the subsistence farm with its natural checks and balances. Not only is the new system more vulnerable to pests and diseases, but many plants, skills and habits associated with a sub-

Drought in the Horn of Africa (Photo: Keystone)

sistence way of life disappear irretrievably. Should famine then occur for whatever reason—political or natural—suffering is likely to be much greater.

The subsistence farmer is a natural survivor under conditions of ecological crisis—his answer to the destruction of his crops by grasshopper or locust is to feed on insects for a time. Development pushes in the opposite direction. I have vivid memories of a village meeting on nutritional problems in Nigeria being forced to disband under the bludgeoning of the bulldog amplifier on a van selling patent medicines for an international pharmaceutical concern. When advertising can penetrate—in this way or via radio—to the most isolated rural areas in Africa, then the imported product of modern manufacture enjoys a powerful advantage over local equivalents. Perfectly acceptable local foodstuffs are traded for volumetrically inferior amounts of processed food or totally inappropriate medicines and tonics, and children malnourished on packaged baby foods then become innocent casualties of a world in which the white-coated image of scientific authority on the advertising hoarding is used to undermine confidence in the old ways for the sake of commercial progress.

In Africa the old relations between man and his environment still have much to tell us. The 'alternative technology' movement in industrially advanced societies is struggling to recover some of the self-sufficient technology of an earlier generation.

In Africa the crops, cultivation practices, crafts and medicines that support a largely self-sufficient way of life are still part of a living tradition, but a major research effort is now required to establish and preserve this knowledge and skill in permanent form. If growing ecological consciousness in science can lead to a greater awareness of and interest in endangered plants and animals, then surely tropical farming systems, pharmacopaeias and technologies deserve at least equal attention. The task is one of trying to encourage, co-ordinate, publish and where necessary to initiate research into aspects of man-land relationships and pre-industrial technology endangered and discriminated against by processes of 'modernization' and economic development in Africa, in the hope that viable 'alternative' strategies of environmental resource management can thereby be identified.

There is, in fact, a fair amount of activity in this sphere in Africa at the present time, but it is a difficult field in which to work for a number of institutional and organisational reasons. Colonially imposed boundaries and *lingua franca* do not follow ecological lines. Scientists in neighbouring countries may be working on comparable environmental problems but fail to benefit from each others' progress for two reasons: firstly, the anglophone/francophone (not to mention lusophone) barrier is even more difficult to transcend in Africa than it

is in Europe, due to lack of language teaching facilities at secondary school, hardly made good by perfunctory courses in French, English and so on for scientists at university level; and secondly, it often appears easier for an African scientist to arrange study leave and research facilities in Europe or North America than in a neighbouring African country. Comparative approaches, in consequence, are rare, and good local case studies tend to remain local in their impact. But above all, the major difficulty lies in the nature of the work, straddling the divide between social and natural science—an unfortunate line of demarcation hallowed not by logic but by usage.

Leaving aside the arid social-antisocial, natural-supernatural science arguments, there are genuine differences of style and method between social and natural scientists—social scientists, for example, are part of what they study and their language leans towards the polemical in the hope of influencing their material for good. Such differences have to be overcome before the two groups can work together effectively. And yet ethnobotany, 'folk' medicine and 'appropriate' technology would be unthinkable without collaboration between, say, biochemists, ecologists, agronomists and engineers on the one hand and linguists, ethnographers and geographers on the other.

The Environmental Review Unit of the International African Institute is one body trying to find its way across these various barriers and obstacles, partly through its bilingual publications programme, which is based on a working relationship between the

Training for the Environment Programme in Dakar and the IAI (the journal *African Environment/Environnement Africain* and the *Special Report* series of monographs and collections of essays are joint ventures, for example), and partly through a research programme which emphasises the involvement of African scientists and scholars in cross-national studies of environmental problems from a comparative and interdisciplinary point of view. The IAI's traditional strength lies in the linguistic and social science fields, but this is being complemented by links with institutions in Africa having strong natural science representation.

Three major research projects are in the course of being established. The first involves the study of nutritional concepts and strategies in subsistence societies and how these are changing, for better or for worse, under the impact of agricultural development. The second is in a way linked, being an attempt by a group of archaeologists, ethnobotanists and ethnographers to investigate the origins as well as the present-day significance of yam cultivation in Africa. The third project involves looking at the agronomic and ecological conceptions of peasant farmers to assess the role they might play in community-based programmes of environmental monitoring and resource management in Africa; it is based on collaboration between IAI research workers in Africa and the Monitoring and Assessment Research Centre of Chelsea College, London, with initial funding from SCOPE, and has resulted in a preliminary report of a Nigerian case study.

The funding of such research, which falls between the natural and the social sciences, poses problems of its own. But with initial results exhibiting great promise for further development along the lines outlined, the hope is that those who normally fund research on either the social or the natural science side will stretch their terms of reference to cover this vital area. The financial resources required are relatively modest but, even so, no single institution or individual can assemble and effectively combine the range of skill and experience required. Inter-disciplinary co-operation rather than intellectual rivalry is the essential pre-requisite. World wide studies by the Disaster Research Unit at the University of Bradford indicate that, while the probability of the occurrence of geophysical and climate disturbances has remained constant over the last hundred years, 'disasters' have doubled.

The conclusion is plain—namely that human communities are increasingly vulnerable to natural hazard, for social rather than natural reasons. Players of the environmental game appear to have two strategies open to them—minimising maximum losses or maximising potential gains. The modern world opts for the latter in the interests of growth and profit. But someone has to pay the price for this aggressive competitiveness, and it is the poor who end up more vulnerable to ecological breakdown than ever before. Good environmental research is difficult to do because it requires a direct reversal of precisely those qualities of individual rivalry and competitiveness that lie at the root of our present environmental predicament. □

## US BUDGET

# Escaping the 'New Realism'

Colin Norman explains how science and technology fare

WHEN President Ford unveiled his election year Budget last week, he said it reflected "New Realism" in government policy in the United States. The new realism turned out, however, to be old-style conservatism in the shape of proposals for massive increases in military spending, swingeing cuts in government expenditure in fields such as health and social services, and tax relief for individuals and corporations. Many of those proposals will be unpalatable to the democratic-controlled Congress—which must act on them before they become law—and thus, as a guide to what will actually be spent by government departments and agencies in the 1977 fiscal year (which begins on October 1, 1976), Mr Ford's budget

figures should be treated with considerable caution.

Nevertheless, the budget, which consists of thousands of pages of facts and figures, richly laced with promises and rhetoric, is an important statement of the Administration's political thinking; it sets out in fine detail the programmes for which Mr Ford and his Administration will seek congressional approval in the coming months. As far as science and technology are concerned, the Administration's thinking seems to be surprisingly expansive in view of the frugality displayed elsewhere in the budget.

The extensive axe-wielding which resulted in keeping the total budget request within Mr Ford's target of

Gerald Ford: 'realist'

\$395,000 million for the federal government next year, left most areas of research and development relatively unscathed. In fact, Mr Ford has proposed hefty increases in several areas

of science and technology, though there are notable exceptions in a few areas, such as biomedical research and space science.

Putting the figures in their best possible light, Dr H. Guyford Stever, the President's science adviser and Director of the National Science Foundation (NSF), noted last week that the budget contains a total of \$23,500 million for research and development and a further \$1,200 million for scientific equipment and facilities. If Congress agrees to the figures, and if all the money is spent, that would amount to an increase of some \$2,200 million (11%) over anticipated expenditures this year. With inflation now reckoned to be about 6 or 7%, the budget proposals would actually result in some real growth in federal support for science and technology.

The increases are particularly unexpected because federal expenditures on research and development fall almost entirely in the portion of the budget which is relatively controllable. More than half the total budget is now spent on such items as pensions and medical payouts for the poor and elderly, which cannot easily be cut, and thus Mr Ford had to look for most of his savings in the relatively controllable section. Using a bit of the rhetoric which is customary on such occasions, Dr Stever told reporters last week that the fact that science and technology fared well in the budget suggests that "this Administration has clearly placed a high priority on research and development for the achievement of national goals".

Two of the Administration's goals—beefing up military technology and securing long-term energy independence for the United States—would swallow up the lion's share of the increases. But another, more surprising trend emerges from the budget pro-

posals. Basic research, federal support for which has dwindled since the late 1960s, would get a monetary shot in the arm, increasing by about 11%. The National Science Foundation's research budget alone is set for an increase of about 20%, and anticipated support for research and development in colleges and universities is set for a 9% boost.

Within that overall budget, the Administration has decided to give its backing to a number of large new science projects. There is money in the budget to begin construction of a \$78 million positron-electron colliding beam device at Stanford University, NASA has been given the green light to begin building a solar spacecraft to study the maximum sunspot activity in 1979-80, and several new energy projects have been proposed.

But there are also bleak spots. Congress and the Administration have not yet been able to agree on the size of the budget for the National Institutes of Health (NIH) for this year, let alone next year, and a lengthy tussle seems inevitable. Ford, in short, wants to trim this year's budget for NIH below what it was in 1975, and he has proposed only a modest increase above the 1975 budget for 1977 (*see later*). Congress on the other hand, wants to increase the NIH budget substantially. The outcome of that tussle will profoundly affect the entire picture for support of research and development by the federal government, particularly in the universities which receive nearly half their total funds for federal research from NIH. Furthermore, NASA has had to defer plans for several key science projects, including the large space telescope, and the Environmental Protection Agency's research and development budget has suffered from the Administration's knife.

Another area which is troubling

many government science agencies is that Mr Ford wants to cut the size of the civil service, which means that although some agencies may get larger research budgets, they will have to administer them with fewer people.

How is Congress likely to treat the science budget? Traditionally, the Administration's budget request is picked over piecemeal by a number of appropriations subcommittees, each of which handles the budget for one or two departments or agencies. Consequently, it has been difficult for Congress to keep track of the size of the total budget, and it has not been easy for Congress to set priorities for some departments in relation to others. But this year, for the first time, Congress has a fully operational budget system to combat those deficiencies. A Budget Committee will establish an overall target figure for the entire federal budget (which may or may not be the same as Mr Ford's target figure), and it will set limits for each individual appropriations subcommittee to stick to. Though the Budget Committee is likely to sympathise with Mr Ford's attempt to reduce the size of the federal deficit—the Administration's budget anticipates that the deficit will shrink from \$76,000 million this year to \$43,000 million next—it will probably attempt to do it in a different way. In short, the major budget battles are likely to centre on the size of the defence budget, with Congress seeking to reduce it below Mr Ford's proposed level, and the size of the budget for the Department of Health, Education and Welfare, which Congress will try to increase. Since those two departments fund the bulk of federal research and development, the outcome of those battles will shape the overall picture for science and technology.

The following are the major highlights in the budget for science and

Table 1 Conduct of research and development of major departments and agencies (in \$ million)

Department or agency	Obligations			Outlays		
	1975 actual	1976 estimate	1977 estimate	1975 actual	1976 estimate	1977 estimate
Defence—Military functions	8,987	9,879	11,198	9,189	9,468	10,762

<b>Total, conduct of development</b>	<b>12,264</b>	<b>14,188</b>	<b>15,683</b>	<b>12,344</b>	<b>13,199</b>	<b>14,929</b>

technology, and the likely congressional arguments.

### National defence

Claiming that "we dare not do less", Mr Ford has proposed a record-breaking budget for the Department of Defence (DOD), amounting to \$114,000 million, of which some \$101,000 million would actually be spent in the 1977 fiscal year. Consequently, military research and development in DOD is set for a whopping budget increase, from about \$9,900 million to \$11,200 million. In addition, Mr Ford has proposed that the Energy Research and Development Administration (ERDA) should spend another \$775 million on nuclear weapons research. Thus, according to Ford's proposals, military research and development would carry off more than half the total science and technology budget, and its share would actually increase.

Most of that money would be spent on weapons development, with ballistic missile projects receiving highest priority. Defence-related basic research is projected to rise from \$330 million to \$383 million. DOD is also under an edict to reduce its civilian staff by some 26,000 which could have repercussions in defence laboratories, and it could also result in more defence work being performed in colleges and universities.

Congress is unlikely to approve an overall defence budget of that size, however, and a major political battle over several weapons programmes should be anticipated.

### Energy research and development

The second area to be favoured with large proposed increases is support of energy research and development programmes, most of which are now clumped in the Energy Research and Development Administration. Mr Ford's budget includes some \$3,200 million for direct energy research and development, together with closely related environmental and basic research. That would amount to an increase of nearly 40%. Congress is not likely to quibble about the fact that the budget for such efforts is increasing by leaps and bounds, but it is likely to question the way in which the money is to be divided between nuclear and non-nuclear technologies.

The Ford budget proposes a sharp increase in spending on fission reactor development and related studies on the fuel cycle, from \$852 million this year to \$1,215 million next. A good deal of that increase would be swallowed up by the Liquid Metal Fast Breeder Reactor (LMFBR) programme, which alone would receive \$655 million next year. That heavy emphasis on the

LMFBR is consistent with a recent policy statement by ERDA administrator Dr Robert C. Seamans Jr, who said that after studying the environmental, economic and technological questions surrounding the breeder programme, he has decided that ERDA should proceed rapidly with LMFBR development. The goal is now to have the first commercial LMFBR in operation by 1993.

The other noteworthy increase in the budget for energy research and development is in the thermonuclear programme. Mr Ford has proposed that the fusion programme should receive a total of \$392 million next year, a massive boost from this year's budget of \$250 million. A large part of the increase is earmarked for the Tokamak fusion test reactor, a major facility under construction at Princeton University which should be in operation by about 1982. The laser fusion programme is also set for a substantial increase, from \$83.6 million to \$101 million.

Large percentage increases have also been proposed for non-nuclear technologies, such as solar energy, development of oil shale, geothermal power, and conversion of coal to liquid and gaseous fuels. But they would continue to receive much less than half the total energy research and development budget.

Congress is likely to question the increased commitment to nuclear energy which the budget entails, but nuclear opponents in Congress probably lack the votes to reduce the nuclear budget substantially. A good deal of noisy skirmishing should be anticipated, however.

### Biomedical research

Once again, the big loser in the federal research and development budget seems to be biomedical research. The situation is, however, greatly complicated by the fact that Congress and the Ford Administration have been unable to agree on the size of the budget for the Department of Health, Education and Welfare (HEW)—of which NIH is a part—for this year, and until they do, the outlook for biomedical research support is very uncertain.

Late last year, Congress passed a bill for HEW which contains very large increases in Mr Ford's original budget request for NIH in the 1976 fiscal year, which is already well under way. Mr Ford vetoed the measure, however, because he claimed that it would fuel inflation and instead, he has now proposed that NIH should receive slightly less money this year than it received last. And the budget he has proposed for 1977 would not even restore NIH to the 1975 level if inflation is taken into account. The various budget pro-

*Dr H. Guyford Stever, NSF Director*

posals for NIH are shown in Table 2.

Congress will try this week to override Mr Ford's veto of the HEW bill. If it is successful, then NIH would receive a hefty budget increase this year. Otherwise, if NIH is funded at the level proposed by Mr Ford, there would be insufficient money available to fund any new projects until next October. In other words, support for new biomedical research would grind completely to a halt. Moreover, NIH budget officials have calculated that Mr Ford's proposed budget for next year would allow them to fund only 37% of the grant applications approved by peer review groups. The outcome of Congress's attempt to override the veto is difficult to predict, but the prevailing opinion on Capitol Hill seems to be that it will be successful.

Nevertheless, Mr Ford's budget proposal for 1977 shows a very significant new trend. For the first time in five years, the Administration has suggested that funds for cancer research should be held in check while support for other areas of biomedical research should be allowed to grow. That suggestion follows months of debate about relative priorities in biomedical research, centred on the fact that cancer research funds have grown by 280% between 1973 and 1975, while NIH's budget for other research has increased by only 20% in the same period.

It is questionable whether Congress will go along with such a redistribution of funds for biomedical research, but at least the proposal would sharpen discussions of research priorities.

Another problem in NIH's proposed budget is that it contains no provision for increases in NIH staff positions. According to Dr Donald Fredrickson, Director of NIH, that restriction could be especially burdensome because NIH is starting up an entirely new institute devoted to study of the ageing process, and it will be forced to do it without any new people.

Congress and the Administration should reach some agreement—or at least a stalemate—on NIH's 1976 budget in the next few weeks. The tussle will then begin over the size of the budget for next year, all of which makes for extremely difficult planning not only at NIH but also in the universities, which now receive about \$1,300 million a year in grants and contracts from NIH.

## The National Science Foundation

The bulk of federal funds for basic research come from the National Science Foundation (NSF). Its budget is therefore closely watched in the scientific community as a barometer of federal support for basic research. About 87% of NSF's money is spent on grants to scientists in colleges and universities.

The budget proposed for NSF would result in a total increase of about 11%, reaching \$812 million. Within that total, NSF's basic research programmes would grow by nearly 20%, while its applied research and education support would either decrease or remain constant. According to Dr Stever, the "specific aim" of the proposed increases "is to counteract the gradual decrease in federal support for basic research which has declined by about 23% in terms of constant dollars since 1968".

The proposed increases in research support would be applied more or less evenly throughout the sciences. No new large projects are planned, but the budget contains sufficient money to continue construction on schedule of the very large array telescope system which is being built in New Mexico.

Usually, NSF's budget attracts little attention in Congress, and aside from minor tinkering by the appropriations committees, the Foundation receives close to the amount of money requested. But last year NSF came in for very heavy criticism on Capitol Hill from Congressmen and Senators who believed that it was either supporting trivial research or that it was developing morally unacceptable school science courses. Consequently, Congress cut NSF's budget for this year, and arranged that basic research bore the brunt of the reductions. Close scrutiny of NSF's programmes can be expected again this year, and Stever warned last week that if the decline in basic research support is to be halted, "Congress must rally round this budget".

## Space science

Once again, the National Aeronautics and Space Administration (NASA) has been cut back and space science has been squeezed especially hard. Dr James Fletcher, the Administrator of NASA, said last week that the proposals for NASA mean that 1977 "will be another year of tight constraints, minimal budgets and limited new activities".

The chief problem is that NASA's total budget is being held approximately constant, while expenditures on the space shuttle are increasing rapidly. The net result is that the shuttle is soaking up a growing share of the Agency's budget, leaving little to spare for space science. Next year, for example, out of a total of some \$3,676 million proposed for NASA, the space shuttle will account for \$1,288 million.

The effects of the squeeze will be particularly severe in the budget for

the Office of Space Science, which is set to shrink from \$417 to \$379 million. Only one major new start has been proposed for next year—a so-called solar maximum mission, a spacecraft which will study solar flares and other phenomena during the period of peak solar activity in 1979–80. The chief casualty is the Large Space Telescope (LST), an optical telescope which NASA hopes to fly on an early shuttle mission in the early 1980s. The LST has been accorded top priority by the Space Science Board of the National Academy of Sciences, and NASA was hoping to begin developing it this year. A start has now been deferred, however, until at least 1978.

Another high priority space science mission which will have to wait for at least another year is the proposed mission to send an orbiter and probe to Jupiter in 1981. Again, there is no money in the budget for that mission, but NASA officials are hoping to make a start in 1978. But one planned venture has been scrapped entirely—the proposal to send a Mariner spacecraft to Jupiter and then on to Uranus. Because there is no money in NASA's budget to start work on that mission next year, the opportunity to make use of a rare alignment of the outer planets to send a spacecraft past Jupiter and on to Uranus will be lost. NASA officials are hoping, however, to reprogramme an already-approved spacecraft due to be launched next year, so that it will fly close to Uranus in 1985 after it swings past Saturn.

In past years, Congress has not made many substantial changes to NASA's space science budget, and there is no reason to expect any difference this year. □

Table 2 National Institutes of Health (in \$ thousand)

Institute or Division	1975 Actual	1976 Revised President's Budget	Vetoed 1976 bill*	1977 President's Budget	1977 change over 1976 President's Budget

\* Does not include money for training grants, which is included in other columns. Congress has voted a separate budget of \$124 millions for biomedical training in 1976, which would bring the total for biomedical research in the vetoed bill to \$2,300 million.

## UK REPROCESSING CONTROVERSY

# Suffering Fuels gladly

It is all down to a Cabinet decision. The media have had their field day, the antinuclear lobbies have voiced their objections and the Select Committee on Science and Technology has declined to investigate the issue. If British Nuclear Fuels Limited (BNFL) gets the green light it wants in the near future the few remaining wrinkles will be ironed out of the deal with the Japanese Enrichment and Reprocessing Group, and irradiated nuclear fuel from Japan will be all but on its way to Britain for reprocessing.

Although spent Japanese fuel is already reprocessed in Britain, few people doubt that the Secretary of State for Energy, Mr Anthony Wedgwood Benn, aimed to give this deal, involving the reprocessing of 4,000 tonnes of fuel over the decade from 1979, a wide public airing. The recent, unattributed "leak" to the popular UK press put the issue before a wider audience than was already following its progress in the up-market newspapers. Speculation over Mr Benn's own attitude added zest to the coverage. And when BNFL followed a public debate in Barrow with another in London this month the presence of Mr Benn ensured a glare of publicity that opponents to the deal could not afford to miss.

But the odds have been stacked against them from the start. Mr Benn has promised that the government will weigh the issues raised by the debate in making its final decision. But the economic benefits which the deal offers, the essential role of reprocessing in Britain's future nuclear programme, and the excellent safety record of the British nuclear industry, all point to a decision in favour of BNFL.

Nor is there any chance that this particular deal will be affected by suggestions that nuclear reprocessing be conducted on a non-commercial basis through an international arrangement. The Pugwash symposium to outline plans towards that end is still some months off; even then it may take several years before proposals percolate through to effective executive levels. The suggestion is anyway irrelevant to concerns about the wisdom of importing foreign radioactive material to Britain. The BNFL reprocessing plant at Windscale in Cumbria, where the Japanese will send their fuel, with its established facilities and 25 years of operational experience, makes it a prime choice for internationally supervised reprocessing.

Most critics believe that reprocessing can actually be avoided altogether.

Some have suggested that benign energy resources be developed to replace nuclear energy, a view more widely regarded as unrealistic, in the short-term at least. Those who accept the need for a continuing reliance on nuclear power, the Pugwash group among them, suggest that a switch to the thorium cycle would provide a viable alternative to reprocessing. That, however, ignores Britain's commitment to the fast breeder reactor. The first FBR will be on-stream by the turn of the century and reprocessing will be an essential part of their nuclear fuel cycle. Moreover, only the most optimistic interpretations of known uranium reserves suggest that there are sufficient natural resources to fuel second generation reactors until FBRs come into their own. The shortfall, it is argued, must inevitably come from reprocessing.

Another factor in Britain's decision, inevitably, will be finance. Throughout the final rounds of its publicity campaign, BNFL has made great play of the deals' commercial advantages. Apart from attracting other foreign customers, mostly in western Europe, the state-owned BNFL could add an estimated £600 millions to Britain's import earnings on completion of the deal. Though the finer details are still under negotiation it is certain that a substantial proportion of that amount—probably between £100–200 millions—will come as a downpayment on the signing of the contract. Payment of the remainder will be spread over the ten-year period covered by the deal. With each consignment sent to Windscale the Japanese will pay an agreed proportion of each batch's reprocessing cost, the total to be made up when the reprocessed material is returned to Japan.

There is no danger that the Japanese fuel will remain in Britain indefinitely. Should BNFL fail to develop the vitrification technique which will allow them to glassify the reprocessed material for relatively safe transport, they will withdraw from the deal and the Japanese will repossess the fuel untreated. The Japanese Enrichment and Processing Group are apparently satisfied with that condition. BNFL confidently expect that their recent step-up of vitrification research will ensure the viability of the process by the mid-1980s.

The reprocessed material will contain a small but significant amount of plutonium, a key element of nuclear weaponry. But suggestions that in completing the deal Britain will thereby

contravene the Non-Proliferation Treaty are ill-founded. The present signatories unanimously recognise that the present agreement is not intended to ban nuclear trade with outsiders; moreover, Japan is in a position to ratify the treaty at any time. In addition, under a system administered jointly by the International Atomic Energy Agency and Euratom, a series of detailed arrangements, to which the parties involved must accede, provide safeguards for nuclear trade agreements. The safeguards are specifically designed to prevent the clandestine diversion of material to military uses, and allow the IAEA to conduct checks at any time. It was by entering into a similar agreement that West Germany was recently able to sell a complete nuclear fuel cycle to Brazil. Similar provisions will apply to the reprocessing deal between Japan and Britain.

There is another area of uncertainty relating to the reprocessing itself. Critics are concerned because the Japanese, who have now adopted the American light water reactor, will send oxide fuel, and not magnox fuel, to Britain. Most of the foreign fuel so far reprocessed at Windscale, coming in the main from Latina in Italy and Tokai Mura in Japan, has been magnox from first generation reactors. The reprocessing of oxide fuel poses greater problems because of the higher activity of the waste. BNFL has gained little experience in oxide reprocessing and what they have is not entirely encouraging. The first oxide reprocessing plant is yet to be built at Windscale, though up until 1973 BNFL reprocessed minor amounts of foreign oxide fuels using a head-end adaptation on the existing magnox plant. The operation was discontinued following a minor incident in which a small cloud of radioactive dust escaped during servicing, contaminating workers. Nonetheless, BNFL aim to have two plants operational by the mid-1980s, handling 1,000 tonnes of material annually. Most of it will come from abroad, according to the company's projections, though all but a small percentage will return to the country of origin.

Trades union officials in Cumbria are eager to see the deal go through. For them at least the issues are clear cut. The deal is likely to create an estimated 2,000 jobs in the area—at the sizeable projected cost of some \$900 million. This the Cabinet may also consider relevant in its deliberations: BNFL itself has deployed the jobs argument in support of its view. But this issue aside, few people doubt the final outcome.

## Journal guidelines

SIR,—In your issue of November 27, you ask for comments on "Journal guidelines", a discussion which you began in your issue of November 6. You may be interested in publishing the experience with our new journal, *Intervirology*, which is owned and operated by the Virology Section of the International Society for Microbiological Societies.

The journal has 12 sections, each with its own editor and specialised board of reviewers, who are listed in each issue. For the first five volumes, each author selected the appropriate section of the journal and submitted one copy of the paper to the Section Editor and a second copy to a board reviewer of his choice. In this manner, the author was confident that his paper was being judged by persons whom he regarded as authorities in the area of the work being presented. The board member sent his review to the Section Editor, who also reviewed the paper and then made the decision to accept, modify, reject, or seek additional, anonymous review. The final judgement as to publication was made by the Section Editor.

At the Third International Congress for Virology held in Madrid in September, it was decided to modify this procedure. To provide a consistent balance between known and anonymous reviewers, authors are now required to send one copy of their paper to an editorial board member. Essentially, the reviewer acts as the friend in court whom the author respects as an authority in the field. The author also sends two copies to the Section Editor, who reads one copy as before, but who now regularly sends out a copy for anonymous review. As before, reviews are sent to the Section Editor, who continues to make the final judgement on publication.

The editors hope that the current procedure will satisfy authors that they are fairly represented in the decision-making process and at the same time will allow for non-personal critical evaluation before a paper is accepted or rejected.

Yours faithfully,  
JOSEPH L. MELNICK  
(Editor-in-Chief)

Department of Virology,  
Baylor College of Medicine,

SIR,—It is extraordinarily difficult to prove the functional value of a complex and subtle social convention such as the preservation of the anonymity of editorial referees. What, for example, is the nature of the 'editorial experience' that Dr C. N. Davies claims (December 18) to confirm his opinion that this long-established custom can be abandoned? His experiment with the *Journal of Aerosol Science* is to be commended; but we shall need to know more about the results before accepting his personal opinion that they are convincing.

Until such empirical evidence is available, I cling rather to the conventional wisdom that anonymity protects the referee from the temptation of softening his remarks to avoid causing personal offence. Most scientists are intellectually conscientious, and will exercise their critical faculties fairly on any paper within their competence; they are seldom (if ever, in my experience) malicious or dishonest. But they know that the delicate competitive/cooperative relationship between colleagues in the same 'Invisible College' cannot stand the stresses that would arise if Dr A had to express, in his own name, in writing, his opinion of the earnest efforts of his rival/friend Dr B. Inevitably, punches would be pulled, and fundamental critical issues would be ducked.

Anonymity is better for all concerned: for the referee, who does not have to mix emotional factors into his intellectual judgements; for the editor, who gets a more honest opinion to guide his decisions; for the reader, who gets more reliable and better expressed papers that have been subjected to a higher standard of criticism; and, strangely enough, for the author who, when his mistakes are pointed out, can vent his chagrin harmlessly in the direction of an impersonal critic without falling into the mortal sin of acquiring a supposed enemy.

The cry against 'authoritarianism' and 'elitism' is, of course, populist in that it appeals to the immediate interest of each individual against the social constraints imposed by the community. But the 'anonymous referee' is only oneself, on the other side of the hill, wearing another uniform. Merton and Zuckermann (*Minerva*, 9, 66; 1971) have found no abuse of the referee system by senior scientists—or whoever the bogies are supposed to be. My own

experience is that the one-way mirror of anonymity facilitates a psychological role reversal, from author to referee, which makes better, more humble, more sceptical scientists of us all, and curbs the vanity and pride of those who claim 'authority'.

This, somewhat schematically and cryptically, is the basis of my assertion that it is a populist folly to disclose the names of referees to authors.

Yours faithfully,

JOHN ZIMAN

University of Bristol, UK

## Unit proposal

SIR,—We would like to propose a unit for electrophoretic mobility ( $u$ ) to replace the current practice of specifying it, for example, as follows:  $u = -2.45 \times 10^{-5} \text{ cm s}^{-1}/\text{V cm}^{-1}$  (+ for cations, — for anions).

In honour of Arne Tiselius, who has done more than anyone else to advance electrophoretic methodology, we propose the adoption of the Tiselius Unit:  $1 \text{ TU} = 10^{-5} \text{ cm s}^{-1}/\text{V cm}^{-1}$  as the unit of the electrophoretic mobility. The above example for electrophoretic mobility will thus be written:  $u = -2.45 \text{ TU}$  in the proposed notation.

This recommendation relies on analogy to the adopted Svedberg Unit  $S$  for sedimentation coefficients ( $s$ ):  $1 S = 10^{-13} \text{ s}$ , where the sedimentation coefficient

$$s = \frac{dr/dt}{\omega^2 r}$$

measures the sedimentation velocity of a particle in a unit centrifugal field, by analogy with the electrophoretic mobility  $u$  measuring the electrophoretic velocity in a unit electrical field.

We will now adopt the Tiselius Unit in our publications and urge others to do so, not only to avoid the wastefulness of the present notation, but also to commemorate the scientist who initiated the far-reaching development of analytical and preparative electrophoretic methodology.

## Self regulation of membrane receptors

from Martin Raff

CELLS communicate with each other largely by means of such chemical signals as hormones, neurotransmitters, and growth factors, most of which bind to specific cell surface receptors. The study of these receptors has been revolutionised in recent years by the development of radiolabelled ligands which bind specifically to particular receptors. One of the rewards of this new technology has been the discovery that the concentration of a ligand can regulate the concentration and/or binding properties of its own receptors on the surface of target cells (see Tata, *Nature*, **257**, 739; 1975). There seems little doubt that this is an important homeostatic regulatory mechanism in cell communication, which, until recently, has been largely overlooked.

The first indication that the binding of a ligand could induce the disappearance of a cell surface macromolecule was provided by Beale (*Int. Rev. Cytol.*, **6**, 1; 1957), who showed that antibodies could specifically remove surface antigens from *Paramecia*, probably by causing them to be shed. Several years later, Boyse and Old and their colleagues observed that antibodies against the Thymus-Leukaemia (TL) antigens caused their disappearance from the surface of thymus and leukaemia cells, both *in vivo* (Boyse *et al.*, *J. natn. Cancer Inst.*, **31**, 987; 1963) and *in vitro* (Old *et al.*, *J. exp. Med.*, **127**, 523, 1968). This phenomenon, referred to as 'antigenic modulation', allowed the leukaemia cells to escape from the host's immune response. A similar phenomenon was later described for H-2 antigens and immunoglobulin (Ig) molecules on mouse lymphocytes (Takahashi, *Transplant. Proc.*, **3**, 1217; 1971). By the use of fluorescein (Taylor *et al.*, *Nature new Biol.*, **233**, 225; 1971) and ferritin-coupled (de Petris and Raff, *Eur. J. Immun.*, **2**, 523; 1972) anti-Ig antibodies, it was subsequently demonstrated that modulation of surface Ig molecules (which serve as antigen-specific receptors) on B lymphocytes was due to pinocytosis of the antibody-

antigen complexes; the same mechanism probably accounts for TL modulation (Yu and Cohen, *J. Immun.*, **112**, 1296; 1974). Antigenic modulation is dependent on time, temperature, and antibody concentration; it occurs progressively over several hours and is prevented by various metabolic inhibitors, but not inhibitors of protein synthesis. If modulated cells are cultured in the absence of antibody, the surface antigens return in 6-24 h; and this requires new protein synthesis (Lor *et al.*, *Eur. J. Immun.*, **2**, 203; 1972). Monovalent Fab fragments of antibodies modulate TL antigens (Lamm *et al.*, *J. Immun.*, **101**, 99; 1968) and induce pinocytosis of surface Ig (de Petris and Raff, *Nature new Biol.*, **241**, 257; 1973), which suggests that modulation does not always require cross linking by the ligand, and this distinguishes it from ligand-induced patching and capping of surface macromolecules, for which cross linking is obligatory (de Petris and Raff, *Nature new Biol.*, *op. cit.*).

Although antigenic modulation has provided insight into some properties of cell membranes, its biological significance is still unclear. Recently, remarkably similar phenomena have been observed when some hormones bind to their membrane receptors; the functional implications here are much clearer, the molecular mechanisms less so. Roth and his colleagues have shown both for mice and for men that when serum insulin levels are chronically elevated (for example, in genetic and induced obesity) there is a striking decrease in specific <sup>125</sup>I-insulin-binding sites on target cells (Kahn *et al.*, *J. biol. Chem.*, **278**, 244; 1973; Soli *et al.*, *J. clin. Invest.*, **56**, 769; 1975). The number of binding sites increases towards normal again when serum insulin is lowered by prolonged restriction of food intake. Conversely, an increase in insulin receptors has been reported in insulin-deficient diabetic hamsters (Hepp *et al.*, *Nature*, **258**, 13; 1975). The loss of specific insulin-binding sites in hyperinsulinemic animals results from a decreased concentration

of surface insulin receptors, rather than from the blocking of receptors by endogenous insulin, the insulin-binding properties of the remaining receptors being entirely normal. Moreover, the *in vitro* exposure of cultured human lymphocytes (line IM-9) to insulin for 5-16 h decreases the concentration of insulin receptors by more than 50% (Gavin *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **71**, 84; 1974). This decrease is dependent on time, temperature, and insulin concentration. If insulin is removed from the culture medium, receptors reappear within 12-24 h and the reappearance is blocked by inhibitors of protein synthesis (Lesniak *et al.*, *Clin. Res.*, **22**, 343A, 1975). Recently, Lesniak and Roth (*J. biol. Chem.*, in the press) have demonstrated that a similar 'down regulation' of surface receptors for growth hormone (GH) occurs when IM-9 lymphocytes are exposed to human GH *in vitro*, and that insulin and GH receptors can be modulated independently on these cells. Inhibition of protein synthesis with cycloheximide produces a small but progressive loss of GH receptors which adds to the receptor loss induced by GH, suggesting that while the cycloheximide inhibits receptor synthesis, GH accelerates receptor loss. Although it has been suggested that insulin-induced receptor loss may be due to weak intrinsic proteolytic activity of insulin (Huang and Cuatrecasas, *J. biol. Chem.*, **250**, 8251; 1975), the mechanism(s) of insulin and GH-induced receptor loss remains to be established.

Another example in which a hormone induces the loss of its own surface receptors has been described by Hinkle and Tashjian (*Biochemistry*, **14**, 3845; 1975). They have shown that GH<sub>3</sub> cells (a cloned line of a rat pituitary tumour) progressively lose surface receptors for thyrotropin-releasing hormone (TRH) when they are exposed to this hypothalamic tripeptide *in vitro*. These cells, which respond to TRH by increasing prolactin secretion and synthesis, show as much as a 75% decrease in <sup>3</sup>H-TRH

binding sites after a 48-h exposure to TRH. Here again, the remaining receptors have the same affinity for TRH as controls, and receptor concentration returns to normal by 96 h after TRH removal. Loss of receptors induced by TRH, like that induced by insulin but unlike that induced by GH, is markedly inhibited by cycloheximide. In this case also, the mechanism of receptor loss is unknown and here it seems unlikely to be due to intrinsic proteolytic activity of the tripeptide hormone.

Recently, the demonstration of receptor regulation by ligands has been extended to a neurotransmitter. It has been known for some time that high concentrations of  $\beta$ -adrenergic catecholamines can induce functional desensitisation of target tissues *in vivo* and *in vitro*, but the detection of changes in the  $\beta$ -adrenergic receptors themselves was delayed by difficulties in preparing specific radiolabelled ligands. The problem of non-specific binding has now been overcome by the use of  $\beta$ -adrenergic antagonists (such as alprenolol) instead of agonists. Using  $(-)^3\text{H}$ -alprenolol as a specific ligand, Lefkowitz and his colleagues have shown that prolonged exposure of frog erythrocytes to  $\beta$ -adrenergic catecholamines *in vivo* (Mukherjee *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **72**, 1945; 1975) or *in vitro* (Mickey *et al.*, *J. biol. Chem.*, **250**, 5727; 1975) leads to progressive and selective decrease (50–70%) in the number of specific alprenolol binding sites without any change in the affinity of remaining sites. Interestingly, whereas  $\beta$ -adrenergic agonists (isoproterenol > adrenaline > noradrenaline) readily modulate their receptors, the potent  $\beta$ -adrenergic antagonist, propranolol, does not; in fact, it prevents the modulation of receptors by agonists. Thus, it seems that receptor occupancy is not sufficient for modulation. The regulation of  $\beta$ -adrenergic receptors differs from that of insulin and growth hormone receptors in that treatment with cycloheximide (*in vivo*, in this case), does not prevent recovery after down regulation (Lefkowitz *et al.*, *Rec Progr. Hormone Res*, in the press), suggesting that  $\beta$ -adrenergic receptors may be reversibly inactivated rather than lost. Axelrod and his colleagues have reported similar observations on the *in vivo* regulation of  $\beta$ -adrenergic receptors of rat pineal cells (Kebabian *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **72**, 3735; 1975). When these receptors are stimulated physiologically (by keeping the animals in the dark to increase the activity in sympathetic nerves supplying the pineal gland) or pharmacologically (by injecting *l*-isoproterenol), there is a rapid fall in specific  $(-)^3\text{H}$ -alprenolol binding sites

which is maximal (70% reduction) by 2 h and which begins to recover by 4 h. Exposing animals to prolonged light (which decreases sympathetic activity) increases the concentration of these receptors. In addition, they have shown that the concentration of specific alprenolol binding sites in the rat pineal normally varies with a circadian periodicity that is inversely related to the cycle of neurotransmitter release (Romero *et al.*, *Nature*, **258**, 435; 1975). Thus, there is little doubt that self regulation of neurotransmitter receptors can occur physiologically.

Teleologically, there are obvious advantages in self regulation of receptors. When cells have 'spare receptors' (that is when the maximum response occurs when only a fraction of the receptors is occupied), as is the case in most of the ligand–receptor systems discussed here, it provides an ingenious way for the cell to regulate its sensitivity to a ligand: lowering the concentration of receptor displaces the dose response to the right while still allowing the cell to make a maximal response if exposed to very high concentrations of ligand. If the cell did not have spare receptors, lowering receptor concentration would lower the maximal potential response of the cell. Just as not all surface antigens are modulated by antibody, however, so not all surface receptors are modulated by their ligand. Nor is this type of modulation the only self-regulatory receptor mechanism: a reduction in receptor affinity for its

ligand with increasing saturation of binding sites (so-called 'negative cooperativity') has been described for a number of hormones (De Meyts *et al.*, *Biochem. biophys. Res Commun.*, **55**, 154; 1973). Moreover, ligand binding is only the first step in the chain of reactions that constitute the cell's response to receptor activation, and it seems likely that regulation in response to varying concentrations of ligand can occur at many of the points in the activation sequence other than at the level of the receptor itself. For example, opiate receptor concentration is not decreased by chronic exposure to high opiate levels (Pert *et al.*, *Science*, **182**, 1359; 1973; Klee and Streaty, *Nature*, **248**, 61, 1974); such 'addicted' cells apparently adapt by increasing the concentration and/or activity of adenylate cyclase to compensate for the rapid and reversible inhibition of adenylate cyclase induced by the initial binding of opiate (Sharma *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **72**, 3092; 1975). Thus, while some cases of 'desensitisation' (= 'tachyphylaxis' = 'tolerance') induced by chronic exposure to high concentrations of hormones, neurotransmitters and drugs, seem to be due to receptor modulation, others are not. In the examples discussed here, where receptor inactivation or loss is involved, the molecular mechanisms remain to be determined. With the technology now available this should not take too long. □

## Invisible astronomy

from David W. Hughes

"WHAT the eye doesn't see the heart doesn't grieve over" is a saying becoming ever less applicable to astronomers. M. E. Bailey, of the University of Sussex (page 290 of this issue of *Nature*) is not of the ranks of radio, infrared, ultraviolet, X-ray and  $\gamma$ -ray astronomers who sightlessly peruse the heavens, but of the smaller band of astronomers who predict the parameters of invisible objects by observing their effect on other stellar and planetary bodies.

One of the first successes in this field was the detection of the white dwarf companion of Sirius A by Bessel in 1844. The wavy paths of astrometric binaries on the celestial sphere has subsequently led to the discovery of planetary companions orbiting about a quarter of the nearby stars to the Sun. Bailey brings us closer to home, into our own Solar System. A great deal is known about the very small and very large objects in interplanetary space.

We observe the small meteorites (diameters normally < 1 m) by the atmospheric trails and surface impact craters they produce when they encounter the Earth. The much larger asteroids, satellites and planets, at the other extreme of the size range (diameters > 1 km) are observable through telescopes. The invisible objects in the Solar System either have sizes between these two limits (10 m < diameter < 1 km) and heliocentric distances less than 5 astronomical units, or are bigger and further away. Both are extremely difficult to detect with telescopes. But when it is considered that Pluto, the faintest planet in the Solar System, has a magnitude +14 and the 200-inch telescope at Mount Palomar, California can detect objects with magnitudes +24 (that is 10,000 times fainter) other planets must have been photographed already, their very small heliocentric velocity as yet rendering them indistinguishable from stars. The detection

of new planets in the Solar System will either be fortuitous or will have to wait until the gravitational effect they have on Pluto and Neptune produces sufficiently large perturbations to enable reasonably accurate predictions of their position to be made.

Cometary nuclei which have a predicted mass range of  $10^{18-3}$  g and a range of diameters from 1 to 100 km have not yet been directly observed. The gaseous coma which surrounds them when they are close to the Sun unfortunately shields the nucleus from observations. Due to the effects of diffraction and contrast the larger comets cannot even be seen when transiting the Sun.

Bailey now suggests a novel way of detecting interplanetary boulders and distant comets. The brightness of stars in the ecliptic plane is continuously monitored to see if the reduction of brightness produced when the star is eclipsed by a nearby interplanetary boulder or cometary nucleus can be detected. This eclipse would last for about the time it takes the object to move its own distance along its orbit; anything from 0.1 s upwards depending on its size and distance from the Earth. A conservative upper limit to the spatial density of the comet cloud, suggests that there are  $10^{10}$  comets in a belt at about 50 AU from the Sun. So using a 1-m telescope, capable of detecting 16th magnitude stars, one of the 1,000 stars visible in the field of view should suffer a short eclipse every 11 h. The problem of picking out this eclipse is an unenviable one.

Another difficulty, inherent in the proposed technique is that a boulder at 1 AU would be indistinguishable from a cometary nucleus at 100 AU. Harwit (*The Zodiacal Light and the Interplanetary medium*, NASA SP 150, 307, 1967) predicts that boulders with sizes between 10 m to 0.5 km have a spatial density of about  $2 \times 10^{-18}$  g cm $^{-3}$ . About  $10^{24}$  g of these boulders are thus distributed through a cloud  $\sim 50$  AU in radius and 2 AU thick centred on the Sun. When these get in the way of distant starlight, eclipses will also occur, adding to the number calculated by Bailey. Interestingly Sekanina (in *Asteroids, Comets and Meteoric Matter*, IAU Colloquium No. 22) proposed that the outbursts in brightness observed from comet P/Schwassmann-Wachmann I were produced by boulder impact. This comet has an orbit which always lies between that of Jupiter and Saturn. Evidence for these boulders could come from observations of their collision with other comets, Trojan asteroids or the minor satellite of Jupiter. This would require a similar experiment to that proposed by Bailey although in this case one would be looking for an increase in brightness,

not a decrease. Sekanina points out however that a  $10^8$  g boulder with a velocity of 60 km s $^{-1}$  burning out in the Earth's atmosphere would produce a fireball of magnitude +12 when observed from a place 4 AU away so again the effect is marginal.  $\square$

## Deeper insights into tRNA

from Stephen Neidle

THE transfer RNAs are molecules of central importance in protein synthesis, forming the essential link between the genetic code in the nucleic acids and developing protein molecules. Thus, the determination of the three-dimensional structure of the various tRNA species by means of X-ray crystallography, has received much attention over the past few years. In spite of considerable effort, however, only one has been both successfully crystallised and analysed—the tRNA coding for phenylalanine which has been isolated from yeast. Structural results emerged almost simultaneously from two laboratories—the MRC Laboratory of Molecular Biology, and the Massachusetts Institute of Technology (see *Nature*, **250**, 699; 1974). The Cambridge (UK) group have been investigating a monoclinic form of this tRNA, whereas the Cambridge (USA) workers have studied an orthorhombic one. These analyses have revealed the molecule as adopting very similar overall shapes in both crystallographic environments; indeed it seems likely that even the finest details of intramolecular conformation and inter-base hydrogen bonding, are very comparable. This large measure of agreement thus implies that the electron-density maps obtained have been essentially correctly interpreted by both groups.

They have now reported further analyses of these two structures, which reveal yet more detail. Indeed, so confident are they of their nucleotide-residue assignments that preliminary atomic co-ordinates have been published (Ladner *et al.*, *Nucleic Acids Res.*, **2**, 1629; 1975, and Quigley *et al.*, *Nucleic Acids Res.*, **2**, 2329; 1975). It is considered that the structures are now basically defined although they have not as yet been analysed to the limit of resolution of the diffraction data (about 2 Å), and the full armoury of structure-refinement techniques remains to be applied. The MRC group have also given an account of the 2.5 Å resolution monoclinic tRNA structure (Ladner *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **72**, 4414; 1975) and the MIT workers have presented further details obtained from their 3 Å electron-

density maps (Quigley *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **72**, 4866; 1975). It is apparent that the two structures are virtually identical except probably at the 3'-acceptor end of the molecule; this is not surprising, as the sequence here seems to be relatively unconstrained and is able to alter its position in going from one crystallographic environment to another.

Both sets of maps are of sufficient quality for purine and pyrimidine bases to be distinguished from each other, this has also meant that the planes in which the bases lie can be more precisely defined than hitherto. Much of the intricate system of base-pairing has been confirmed, little of which is of conventional Watson-Crick type. It has also become apparent that the hydroxyl groups of many of the riboses play a very important part in helping to augment these tertiary interactions by acting as hydrogen-bond acceptors. Perhaps unexpectedly, it seems that some riboses (possibly as many as ten), adopt a C2'-endo conformation instead of the normal C3'-endo one; details of this will, however, have to await the results of the high-resolution refinements already in progress.

Several new interactions have been revealed, particularly in the neighbourhoods of the highly intricate joins and junctions between loops and stems. For example, guanine-45 seems in both models to be hydrogen-bonded to guanine-10 at the anti-codon arm-D-stem junction. Guanine-10 is itself involved in a Watson-Crick base pair with cytosine-25, thus forming a triplet of bases. Earlier interpretations of the interactions in these junctional regions had several disputed points, but these have now been largely resolved.

In retrospect, the differences and indeed difficulties in map interpretation, were not unexpected bearing in mind the great complexity of the structures, and the fact that these were the first polynucleotide structures to be examined by single crystal analysis. Among the many other points of interest which have emerged from these latest interpretations, is a neat description by the MRC group of a guanine-uracil base pair, which to date has only been observed in this yeast tRNA<sup>Phe</sup>. Such a base pair was predicted 10 years ago by Crick in his 'wobble' hypothesis, and the glycosidic bond conformational change required to accommodate the wobble seems to be as he suggested. Quigley and his colleagues have detected the probable locations of a number of metal ion sites, which are positioned to interact favourably with phosphates of the polynucleotide chain; as they suggest, such bindings may well play a part in stabilising the chain folding.

A question central to any discussion

THE annual cycle of aggressiveness now demonstrated to occur in several species of rodent (Turner and Iverson, *Ecology*, **54**, 967; 1973, Krebs and Myers, *Adv. ecol. Res.*, **8**, 238; 1974) may have an ecological and even evolutionary function of much wider significance than has hitherto been thought. The species *Clethrionomys gapperi* and *Microtus pennsylvanicus* are found in forest and grassland habitats respectively and seldom occur in the same habitat (Grant, *A. Rev. ecol. Syst.*, **3**, 79; 1972). When populations are not expanding rapidly dispersal is minimal. During periods of expansion considerable dispersal occurs resulting in invasion of normally ignored habitats Iverson and Turner reported such an event occurring when enlarged *Clethrionomys* populations invaded *Microtus* habitats (*Am. Midl. Nat.*, **88**, 440; 1972), but now it has been shown that either species can be the invader.

Working in spruce forest and old field habitats in Manitoba, Turner, Perrin and Iverson have analysed the components of the tidal effect of an invasion of a *Clethrionomys* forest by *Microtus* and shown the part played by the annual cycle of aggressiveness in returning the situation to normal (*Can. J. Zool.*, **53**, 1004;

1975). During the late autumn of 1973 a significant influx of *Microtus* into forest land was observed. Co-existence with resident *Clethrionomys* occurred throughout the winter but came to an abrupt end in May 1974. Intraspecific aggression of both species fell to its lowest during the winter, and with it the level of inter-

## Rodent aggression

from our Animal Ecology Correspondent

specific aggression. In paired encounters neither species was dominant over the other. Dominance was assessed by scoring the number of aggressive acts performed per standard encounter (*Nature*, **247**, 254; 1974). At the start of the breeding season both species became reproductively mature and both intra- and interspecific aggression increased four-fold.

Curiously enough, early in the breeding season *Microtus* became markedly dominant, winning nearly all encounters. That they did not displace the resident *Clethrionomys* is thought by Turner and his colleagues to be due to the (unspecified) advan-

tages provided by the home habitat. By early May all the infiltrators had gone leaving the forest once more to the *Clethrionomys*. It seems that co-existence is possible only when interspecific competition is at a low ebb and that it is linked to the reproductive cycle. If resource partitioning is of selective advantage in the summer, why is it not of equal importance in the winter? Food for these species is never likely to be limiting although it will fluctuate in abundance during the year, so summer food shortage is unlikely to be the wedge driving each species back to its own habitat. The sudden cease in hostilities, coinciding with the start of widespread dispersal in early autumn, means that very many more individuals survive for much longer than would be the case if temporary, out-of-range residence was not possible. This has two main effects; one is to allow emigrés to continue their search for fresh pastures, with all the evolutionary advantages this may confer (Christian, *Science*, **168**, 84; 1970); the other is to maintain a higher biomass of rodents during the winter than would otherwise be possible. This allows the existence of larger stocks of predators and a correspondingly higher secondary productivity.

of the biological significance of these structural findings is whether the conformation observed in the solid state is a representation of that existing in solution. Chen, Giege, Lord and Rich (*Biochemistry*, **14**, 4385; 1975) have attempted to answer this point by examination of the laser Raman spectra of yeast tRNA<sup>Phe</sup>. This technique has the advantage over others in that spectra can be observed in both solution and crystal; furthermore, conformational changes can often be readily detected. The observed spectra are almost identical in the two environments. Chen *et al.* also examined the spectra from both the orthorhombic crystals and a hexagonal modification, which again had essentially the same pattern of Raman frequencies and intensities. They conclude therefore that the tertiary structure of this tRNA is not only conserved in different crystal forms, but most importantly, in solution.

The next stages in the tRNA saga must be to relate this structure to its multifarious biological functions. Present attempts are necessarily speculative. Ladner *et al.* have rightly drawn attention to the quite pronounced segregation of the invariant and variable bases at several places in the crystal structure, which they suggest may be involved in synthetase recognition in one instance, and in ribosomal binding in another. It is to be hoped that the

structural studies on synthetases now in progress will answer some of these questions. Kim has also recently turned his attention to synthetase binding (*Nature*, **256**, 679; 1975) and has suggested that symmetry recognition might be important. He has observed that the tRNA crystal structure has approximate two-fold symmetry; sequence data on synthetases suggest that the subunits might also be internally organised into two domains related by two-fold symmetry. It was then straightforward to construct hypothetical symmetrical binding schemes for the two sets of domains in the two molecules; at present, these seem not implausible. □

## Making galaxies from stars

from M. G. Edmunds

GALAXIES are made of stars. Perhaps the simplest way to model the formation of a galaxy is to imagine a random distribution of stars in space, add a suitable amount of energy, and let the gravitational forces between the stars go to work. Provided not too much energy is put in, the stars will form a more spatially condensed system—a galaxy. Recently J. R. Gott (*Astrophys. J.*, **201**, 296; 1975) has described some

interesting model building of this social behaviour of stars.

Elliptical galaxies are observed to be spheroidal systems of stars which contain very little gas. Despite considerable variation in the flattening between different galaxies, the distribution of light from the galaxies as a function of distance from the centre of each system is remarkably similar. This observational relation, originally discovered by Hubble (Hubble's Other Law!), can be used to infer the radial distribution of the mass density of stars within a galaxy. Previous simple models of the gravitational contraction, or "collapse", of elliptical galaxies have given too rapid a decline of the density of stars with radius. The disagreement has led other workers to build more complicated models which introduced star formation and gas to affect the dynamics of the collapse. Gott has now resolved the discovery with observation, relying on stellar dynamics only. He assumes that small fluctuations occur in the density of a smooth Universe as it expands from the Big Bang. Stars form, and the stars in a region of high density collapse together to form a protogalaxy. The new feature of his model is a continuous increase in the mass of such a protogalaxy by the infall of stars from surrounding regions. One other process is invoked: as the Universe expands, a protogalaxy can experience gravitational tidal forces from

other protogalaxies nearby. Gott uses a very simplified model for the tidal interaction, but it nevertheless suggests two important results. The interaction will limit the final size of the galaxies and also impart angular momentum which will determine the flattening of each system. Although other models can account for the observed structure of ellipticals, Gott claims simplicity in that his models fit the data with fewer arbitrary parameters. His method is also attractive because it does not introduce any assumptions about star formation, other than that it occurs before collapse of the protogalaxy. Models which introduced star formation as a variable had to employ very *ad hoc* assumptions since no coherent theory of star formation exists.

The step from a theory of elliptical galaxy formation to a theory of spiral galaxy formation is a dangerous one. The main feature of spiral galaxies is a flat spiral disk of gas and bright young stars. A popular view, restated by Gott, is that spirals form if there is a significant amount of gas remaining in the system during the initial collapse, contrasting with the formation of ellipticals where effectively all the matter is incorporated into stars before collapse. The stars behave as in the collapse of an elliptical system, and a spheroidal distribution forms. But the gas interacts strongly with itself, rapidly dissipating much of its kinetic energy and forming a thin disk within the spheroidal "halo" of stars, rather like the meat inside a hamburger. Subsequent birth of stars from the gas gives the bright observed disk, but these stars have fairly small velocities and stay in the disk since the kinetic energy of the gas out of which they formed has been dissipated during the collapse. The halo of old stars remains.

The idea that massive haloes containing an equal or major part of the mass exist around the disks has become respectable as a result of several studies of the stability of the disks. A massive halo can stop the rapid evolution of a disk of stars into the bar-like structures which occur in numerical simulations of the stellar dynamics of disk systems. Since it is believed that spirals are not just a very transitory stage of galactic evolution, such instability of the disks is undesirable. In Gott's picture of galaxy formation the existence of such stabilising haloes around spirals is quite natural. But an attempt to determine the scale of the halo around our own Galactic disk by Maarten Schmidt (*Astrophys. J.*, **202**, 22; 1975) implies that the mass of our halo is much less than the mass of our disk. Stars in the halo possess on average much higher velocities relative to Earth than do disk stars. Schmidt uses a high velocity criterion to

identify halo members near the Sun. By making fairly reasonable assumptions about the relation between mass and luminosity for these old halo stars he infers that the local density of halo stars is at least an order of magnitude less than the mass required to stabilise the disk. The statistics of such an investigation are necessarily poor, but his result certainly indicates that mechanisms to stabilise the disk, other than the existence of a massive halo, should be sought. The result also implies that for spirals like our own Galaxy, Gott's simple stellar dynamics of spheroidal collapse which seems to work so well for ellipticals, is only a small part of the formation process. It is the material that forms the disk, rather than the halo, which will dominate the gravitational interactions during the collapse, which together with gas interactions will make a theory of spiral galaxy formation considerably more complicated. □

## Superfluid $^3\text{He}$ : an impediment removed

from P. V. E. McClintock

WITH the publication in *Physical Review Letters* (**35**, 615, 1975) of a comment by Webb, Sager and Wheatley of the University of California at La Jolla, one of the principal impediments to the identification of superfluid  $^3\text{He-B}$  as the state originally proposed by Balian and Werthamer (*Phys. Rev.*, **131**, 1553; 1963) seems to have fallen away.

Since its discovery in 1972, there has been an explosion of theoretical endeavour towards gaining a satisfactory understanding of superfluid  $^3\text{He}$  and, considering the inherent difficulties of work in the relevant temperature range below 2 mK, a quite astonishing range of experimental data has also been acquired. As a result it is now known that in a weak magnetic field there are two principal superfluid phases: the A-phase, which is stable only within a limited range of temperatures ( $T$ ) for pressures ( $P$ ) between 22 bar and the solidification pressure of 35 bar; and the B-phase, which occupies the greater part of the  $P$ - $T$  phase diagram for the liquid. Both phases exhibit complicated magnetic properties, and both are highly anisotropic, being in many respects akin to liquid crystals, with the orientations of their axes of anisotropy being determined by such factors as the applied magnetic field, thermal currents, and the proximity of the walls of the containing vessel.

The present theoretical picture of the superfluid phases, which has been constructed mainly on the basis of their observed magnetic properties,

portrays the liquid as having much in common with the superfluid electron gas in a superconducting metal, in that the superfluidity arises through the formation of pairs of particles. In contrast to the superconducting situation, however, it has been clear that the  $^3\text{He}$  atoms form pairs whose relative angular momentum is non-zero. Thus, the two atoms of a pair can be regarded as orbiting around each other somewhat like a diatomic molecule (but the analogy should not be pressed too far: unlike a diatomic molecule, the correlated pair of  $^3\text{He}$  atoms spends most of its time separated by distances very much larger than the average interatomic spacing in the liquid). Each pair in the superfluid is in the same quantum state. Thus, to change the state of one pair, for example by setting it in uniform translational motion, would involve simultaneously altering the state of every other pair which clearly is a relatively difficult thing to do, thus providing an insight into the origin of the observed superfluid properties.

Further complications arise because the  $^3\text{He}$  atomic nucleus carries a net spin and hence an associated magnetic dipole moment. Much of the theoretical effect has been aimed at discovering exactly how the orbital angular momentum of a pair is correlated with the orientations of its nuclear spins, as well as at finding the answer to the more fundamental question as to the magnitude of the orbital angular momentum itself. It became accepted at quite an early stage that the A-phase was probably in the state first suggested by Anderson and Morel (*Phys. Rev.*, **123**, 1911; 1961) and subsequently developed and justified in more detail by Anderson and Brinkman (*Phys. Rev. Lett.*, **30**, 1108; 1973). In this (ABM) state, the pair orbital angular momentum is unity, and the nuclear spins lie in the plane of the orbit either parallel ( $\uparrow\uparrow$ ) or antiparallel ( $\downarrow\downarrow$ ) to an externally applied magnetic field; there are no pairs with opposed ( $\uparrow\downarrow$ ) nuclear spins. The B-phase was identified, although with less certainty, as a form of the (BW) state originally proposed by Balian and Werthamer in which the pair angular momentum is again unity, but all three possible spin states ( $\uparrow\uparrow$ ,  $\downarrow\downarrow$ ,  $\uparrow\downarrow$ ) are present and the correlation of spins and orbit is somewhat more complicated.

Associated with both the A and B phases are characteristic frequencies  $f_A$  and  $f_B$ , dependent on  $T$  and weakly on  $P$ , which arise when the equilibrium configuration of the liquid in a magnetic field is slightly disturbed. These frequencies can be measured directly in longitudinal nuclear magnetic resonance (NMR), can be deduced from the shift of the transverse NMR frequency from its value in normal (non-

superfluid) liquid  $^3\text{He}$ , or can be measured from the magnetic ringing which follows a small incremental change in the applied magnetic field. A crucial test of the validity of the ABM and BW state assignments which was suggested by Leggett's calculations (*Phys. Rev. Lett.*, **31**, 352; 1973) involved measuring the ratio  $f_B/f_A$  at the A-B transition: according to his equations, the quantity  $(f_B/f_A) \times (\chi_B/\chi_A)$  should be precisely equal to  $(5/2)^{1/2}$ , or about 1.58. Here,  $\chi_A$ ,  $\chi_B$  are the static magnetic susceptibilities of the two phases.

Subsequent magnetic ringing experiments at La Jolla by Webb, Kleinberg and Wheatley (*Phys. Rev. Lett.*, **33**, 145; 1974) gave a value for  $f_B/f_A$  of  $1.9 \pm 0.1$  near the polycritical point (at which the A, B and normal phases are in mutual equilibrium) where  $\chi_A = \chi_B$  to an excellent approximation. This unwelcome result received support from work at Helsinki by Ahonen, Alvesalo, Haikala, Krusius and Paalanen who reported (*Phys. Lett.*, **51A**, 279; 1975) that, for similar conditions of  $P$  and  $T$ ,  $f_B/f_A = 1.93 \pm 0.05$ . These results were disconcerting in that they seemed unambiguously inconsistent with  $^3\text{He-B}$  being in the BW state, assuming that one had accepted as correct the identification of  $^3\text{He-A}$  with the ABM state.

On the other hand, Osheroff (the original discoverer of the superfluid phases during his PhD research at Cornell University) and the group at Bell Laboratories, working at the solidification pressure in a compressional cooling cell, were persistently reporting NMR results which seemed entirely consistent with the BW identification of B-phase. In particular, Osheroff (*Phys. Rev. Lett.*, **33**, 1009; 1974) found very close agreement with Leggett's  $(5/2)^{1/2}$  prediction. Thus, a situation arose where Bell Laboratories data at 35 bar seemed to support the BW state, whereas data taken at lower pressures in two other laboratories appeared to show that this state assignment was incorrect.

The overall situation was particularly disquieting because, as Leggett pointed out (*Rev. mod. Phys.*, **47**, 331; 1975) it occurred "in an area where neither theory nor experiment appears to have much room to manoeuvre". In the event, the theory and the Bell Laboratories group have stood firm and it is the experimenters at La Jolla who are doing the manoeuvring, as may be seen in the comment from Wheatley's group: their new measurements of magnetic ringing, again near the polycritical point but using a different experimental geometry, have yielded results which appear to be in reasonably good agreement with Leggett's  $(5/2)^{1/2}$  factor. It is said that a similar

## Dynamo attack

from Peter J. Smith

WHEN the principle of the self-exciting dynamo was put forward in the late 1940s to explain the origin of the Earth's magnetic field, the core motions required to maintain the dynamo were attributed to thermal convection generated by radioactive heating. Much later, Malkus (*J. geophys. Res.*, **68**, 2871; 1963) proposed alternatively that the driving force on the core could be the Earth's precession. The idea of precession-induced flow was not new, for the early dynamo theorists had considered and rejected it. What Malkus did was to show that the original reasons for rejecting a precession-driven dynamo were unsound, since which time both convection and precession have been widely accepted as serious contenders for the role of core driver.

Now, however, Rochester *et al.* (*Geophys. J.*, **43**, 661; 1975) report calculations which appear to prove that the power to be derived from precession is at least an order of magnitude too low to stir the core into stable flow. This disagreement with Malkus would be interesting in its own right; but the report is all the more remarkable in that Rochester and his colleagues go on to criticise Malkus severely not only for his result but for the way he obtained it. Specifically, they accuse Malkus of appealing to dubious analogies, of claiming agreement with previous work where no such

agreement exists, of publishing inconsistent equations, of error in mathematical logic, of mathematical oversimplification and of numerical errors, among other things. They further object that in later articles Malkus has not only ignored the few published objections to his 1963 work, but has repeated the errors and retracted nothing.

This is the most severe attack to have appeared in the Earth sciences for many years and raises ghosts from another century. But whether or not one agrees with the form of the criticism, it would be a pity to overlook the serious issue it raises. Many people have come to believe in the feasibility of a precessionary dynamo because they have read Malkus's conclusion but not the arguments on which it is based. The problem is that studies in this field are so esoteric that only a handful of people in the world can understand them; indeed, even Rochester and his colleagues claim not to be competent to deal with all the points involved. As they themselves point out, under such circumstances the rationale for avoiding unpleasant criticism, as described by Ravetz (*Scientific Knowledge and its Social Problems*, OUP, 1971), breaks down and myths develop.

The question now is: is the precessionary dynamo such a myth or not? For the irony is that most Earth scientists will find the detailed arguments of Rochester *et al.* no easier to understand than those of Malkus, and will, as before, have to be content with the conclusion.

manoeuvre has also been carried out in Helsinki. The reason for the earlier discrepant results is not yet entirely clear, but they can perhaps be regarded as a reminder of how much is still not properly understood about the liquid.

The new measurements at La Jolla, which provide a welcome vindication for the work of Osheroff and the Bell Laboratories' group, may be regarded as greatly strengthening the present state identifications of both superfluid phases of liquid  $^3\text{He}$  and will, no doubt, have been received with sighs of relief from the many theorists working in the field □

## Regulatory genes and quantum evolution

from A. Hallam

THE abrupt appearance of higher taxa in the fossil record has long been something of an enigma to palaeontologists. Although it is true that temporal sequences of fossils provide some of the

best evidence of evolution, Darwin himself was somewhat embarrassed by the sparsity of transitional forms, which he attempted to explain away by invoking numerous erosional breaks in the sequence of strata bearing the fossils. Since Darwin, many of these 'stratigraphic' gaps have been filled as a result of research throughout the world by numerous people, yet the quantum jumps between phyla and lower taxa by and large remain. A few decades ago Simpson made a valiant attempt to grapple with the problem by putting forward an ecological model of 'quantum evolution' consistent with current genetic theory. This involved small populations of particular species crossing some environmental threshold into a new adaptive zone (certain mammals re-entering the sea for example), whereupon there ensued rapid evolutionary radiation and hence pronounced morphological divergence from the parent stock.

Valuable as Simpson's ideas have proved, major problems and uncertain-

ties have remained about the underlying genetic control, and further attempts must be made to square the facts of palaeontology with the new knowledge and insights gained from molecular biology. Evolutionary genetics has been primarily concerned with structural genes, those genes which are transcribed into RNA, leading to the synthesis of particular proteins and enzymes. It turns out however that there are striking similarities in the basic proteins and enzyme activities throughout the organic world, from primitive prokaryotes to mammals, which vastly outweigh the differences. The enormous differences within the animal and plant kingdoms are much more a matter of organisation and structure. This suggests to Valentine and Campbell (*Am. Sci.*, **63**, 673; 1975) that the evolutionary divergence of major and perhaps even minor taxa has been effected mainly by changing patterns of gene regulation rather than the mere substitution of amino acid sequences in proteins.

The regulatory model proposed for prokaryotes (bacteria and blue-green algae) by Jacob and Monod, involving operator and repressor genes, has been verified in many particulars, but gene regulation in the much more complex eukaryotes (the rest of the organic world) is far less well understood. Valentine and Campbell favour the general regulatory model for higher organisms put forward by Britten and Davidson (*Q. Rev. Biol.*, **46**, 111; 1971). 'Sensor' genes receive a stimulus, probably hormonal, and cause 'integrator' genes to transcribe. The transcription product, activator RNA, is detected by 'receptor' genes, which in turn cause structural genes to transcribe. Whole batteries of receptors, which need not be mutually exclusive, operate under the control of a single integrator, and a hierarchy of sets could be controlled by a series of master sensors. It is evident that mutations affecting regulatory genes, together with chromosomal rearrangements, could create in a geologically short time a wide variety of novel patterns involving large numbers of structural genes.

In broad outline evolution can be envisaged to have proceeded in a number of major steps, each involving a repatterning of genes in new combinations and expansion of the regulatory apparatus, as cell types differentiated and complex body-layer and organ systems progressively developed. Thus for the animal kingdom the sequence is: protozoans; diploblastic metazoans (sponges, jellyfish); triploblastic metazoans (flatworms); primitive burrowing coelomates (many worms); advanced coelomates, often with skeletons. Each successive step involved significant addition of new in-

## A hundred years ago

OUR readers no doubt know that we have a younger French sister who appears under the name of *La Nature*. We have just received from Germany a specimen of another of the family, rejoicing in the name of *Die Natur*. This seems, however, to be a new series of an old-established journal, but whether it has always appeared under its present name we cannot make out. It is conducted by Dr. Otto Ule and Dr. Karl Muller, of Halle, is mainly devoted to natural history, and the number sent us contains several interesting articles; among these is one on the African Steppes, by Dr. Ule. from *Nature*, 13, January 27, 256; 1876

formation to the regulatory apparatus and creation of batteries of structural genes in new combinations. The fossil record indicates that all the steps were accomplished by the end of the Cambrian, some 500 million years ago, when all but two of the living phyla that are well skeletonised had already appeared. This does not mean that most palaeontologists are necessarily only concerned with the equivalent of philosophy's 'footnotes to Plato', because there is still a vast amount to be discovered about the detailed patterns of evolution as revealed by fossil distributions in time and space. The Valentine and Campbell paper is valuable not so much in prediction as in providing a satisfying interpretive framework for further research. □

## Rapid quenching: second harvest

from Robert W. Cahn

The Second International Conference on Rapidly Quenched Metals was held at the Massachusetts Institute of Technology on November 17-19, 1975. It was organised by Professor N. J. Grant, of MIT, and Professor B. C. Giessen, of Northeastern University.

WHEN a canny farmer ploughs a new field, the first harvest will as likely as not be bounteous; but the second harvest defines the long-term value of the land. The Conference was dedicated to Pol Duwez, the American metallurgist, who first opened up the field of

rapidly quenched metals 15 years ago; a rich first harvest was reaped in 1970 during the First Conference, and now the second has proved that he made a sound investment.

The Conference was immediately followed by a Workshop (held at Northeastern University, Boston) devoted to the applications of amorphous alloys. These materials—also known as metallic glasses—are merely one subcategory of rapidly quenched metals, but the fact that two days were entirely devoted to them reflects the organisers' judgment, vindicated by the Conference and Workshop, that the corn now grows tallest in this corner of the field.

The first Conference, in 1970, was largely concerned with extended solid solubility and with anomalous intermetallic phases resulting from splat-quenching of alloy melts. Fewer papers this year dealt with these concerns than one would have foretold then. Some of these were concerned with steels: groups at Cambridge (UK), Tohoku University (Japan), and the University of Pennsylvania (USA) examined the behaviour of splat-quenched steels, both in their initial state and after subsequent transformation: crystallography, morphology and kinetics were all investigated. The Cambridge group concentrated on familiar steels such as Fe-Mo-C steels, and observed solubility extension in ferrite, retained austenite and a number of unfamiliar carbides: the steels were at all stages crystalline. The others examined Fe-P-C, one of the transition metal/metalloid combinations which become amorphous on quenching, and investigated the details of subsequent crystallisation. This is an area where much more research is now needed, with good prospects of industrial applications.

Aluminium alloys continue to be the favourites among those who prefer to investigate crystalline forms of metastability. Some of these have reached the verge of industrial use. A group at the Battelle Institute in Frankfurt (Germany) have scaled up a technique for splat-quenching and compaction of Al-Fe alloys (for some years now the preferred alloys for practical application), further alloyed with Mg, Mn and Cr. The product is not only very strong, even at 300 °C, but—like a number of other chromium-bearing splat-quenched alloys—extremely resistant to corrosion: there was no detectable attack by superheated seawater at 150 °C. Some applications are immediately apparent. A group from the University of Sussex (UK) showed how a plasma-spraying gun, with improvements to help keep the deposit cool, can be used to spray highly super-saturated and thus extremely strong Al-Cu alloy sheets.

An impressive paper from Battelle

Pacific Northwest (USA) showed how a large sputter-deposition apparatus can be used to make sizeable artefacts of metastable materials, including alloy glasses. This seems to be the only available way of making such objects other than in thin-sheet form.

Surprisingly little attention was paid to the regularities governing solubility extension and metastable intermetallic phases: one paper from Northeastern University identified some relationships between stable and metastable ordered intermediate phases, and a major paper from Carnegie-Mellon University (USA) pinpointed the influence of 'electronic factors' à la Hume-Rothery on the extension of solid solubility in various alloy systems. In summary, unfavourable size factors can be overcome by rapid freezing but unfavourable electronic factors cannot.

Over the past five years there have been notable developments in quenching techniques. A good deal of interest was manifested in the technique of plasma-spraying. The high point, however, was a paper from the Battelle Laboratories in Ohio (USA) describing a patented new method for making rapidly quenched ribbons. A rapidly rotating contoured wheel dips into a metallic melt, either subjacent in a crucible or pendant over the wheel from a rod of solid metal: the wheel 'spins' out a ribbon which lifts clear after it has frozen. The ribbon can either be spooled or else the wheel can be provided with a series of circumferential nicks; when that is done, a shower of short filament lengths is generated, ready to substitute for chopped fibre in (for instance) reinforced concrete. This technique has already been licensed and is soon to go into industrial production. Though the method has required a good deal of fine tuning it has the essential simplicity of all classic production techniques and will be a significant rival to the roller-casting technique, already in commercial use by Allied Chemical Corporation to make their 'Metglas' amorphous alloys. That Corporation's scientists were much in evidence during the five days, and a number of new compositions were announced, in particular Metglas 2605 ( $\text{Fe}_{80}\text{B}_{20}$ ), notable for high magnetic permeability and high strength, and a range of Be-Ti-Zr glasses such as the high-strength Metglas 0422,  $\text{Be}_{40}\text{Ti}_{50}\text{Zr}_{10}$ .

Much attention was devoted to the structure of amorphous alloys (a piquant concept, since 'amorphous' derives from the Green root for 'formless'). Several laboratories, notably the Tohoku group, the Technical University of Berlin and the University of Paris-Sud, have firmly established by X-ray and neutron diffraction and other methods that alloy glasses have

very pronounced compositional short-range order, as had been suspected. The interest evident five years ago in computer-modelling of alloy glasses based on 'dense random packing' (with a view to comparing computed and experimentally derived pair distribution functions) has been fully maintained, while the rather pointless semantic controversy between the 'true amorphous' and 'microcrystalline' models shows signs of attenuating. In this field of research, scientists from the IBM Watson Research Centre at Yorktown Heights (USA) and the long established group at Harvard are making major contributions.

More than half of the Conference/Workshop was devoted to the mechanical and magnetic properties of alloy glasses. The combination of very high strength with appreciable ductility of these materials has been well documented, and no surprises emerged. Interest is beginning to focus on the influence of annealing, below or above the crystallisation temperature, on mechanical behaviour. One intriguing observation was that annealing can embrittle phosphorus-bearing, deformed, alloy glasses, and controversial evidence suggests that phosphorus diffuses to shear bands and promotes fracture.

The new Be-Ti-Zr ribbons will be of particular interest. One novelty was the observation that fracture toughness is a sensitive function of ribbon thickness, and is an optimum for a thickness less than the maximum which can be fabricated. This is not as yet understood. Although the makers of 'Metglas' ribbons have for some time now emphasised the role of their product as a reinforcing fibre, this Conference heard the very first public account of a systematic attempt to put this claim into effect. A group at Pratt & Whitney Aircraft experimented with epoxy resins reinforced with one of the commercial ribbons, up to 40% volume fraction; though the resin-ribbon bond was weak, good reinforcement was attained both longitudinally and transversely. It is astonishing that this should be the first published investigation of its kind, and that no accounts of filament-winding have yet appeared.

The topic which now excites the greatest interest, both scientifically and industrially is the ferromagnetic behaviour of various amorphous alloys based on iron and nickel, and to a lesser extent cobalt. A great many contributions centred upon this, especially an impressive cluster from Bell Telephone Laboratories (Murray Hill, USA) and another from the General Electric R and D Centre at Schenectady (USA). An academic group at the University of Pennsylvania and the

extremely energetic Japanese group at Tohoku University are also active in this field. Increasingly, the various groups are manufacturing their own glassy materials. (If two individuals may be picked out for sheer collaborative productivity in research on amorphous alloys, honours should go to H. S. Chen of Bell Telephone and T. Masumoto of Tohoku).

The major group of alloy glasses—including now the new commercial  $\text{Fe}_{80}\text{B}_{20}$ —has high permeability, low coercivity and reasonably good performance at high frequencies. Materials with zero magnetostriction and consequently extremely low anisotropy energies and high permeabilities, are now routine. A wide range of magnetic properties is in fact attainable in one and the same alloy, merely by changing the details of the magnetic annealing treatment.

Magnetic domains are detected in spite of ultra-low anisotropies and the ribbons are sensitive to handling, though less so than materials such as crystalline permalloys (as one exasperated scientist remarked, one dare not look at permalloy for fear of spoiling its permeability!) Roller-cast ribbons have periodic variations of magnetic behaviour, related to periodic variations of internal stress introduced during production. The intimate symbiosis between minutiae of manufacture and magnetic behaviour, long familiar in the world of magnetic materials, is again very much in evidence. A newly discovered family of glassy alloys based on Fe/Th compositions and made by massive sputter-deposition, prove to be strong permanent magnets. Here high anisotropy appears to stem from local variations in composition and structural order.

As the GE group in particular indicated, there are in principle very extensive magnetic applications for alloy glasses in industry, especially the high-permeability kind. Filter chokes, transducers, loading coils, fluxmeters, magnetic amplifiers, L-F inverters and indeed transformers are all candidates. Much of the ground work in establishing suitable compositions and forms of magnetic annealing has been done. There is just one remaining obstacle, but it is a major one! Up to the present, alloy glass ribbons can only be made a few millimetres wide. For most applications, wide sheet is essential. The commercial people present were extremely tight-lipped about this crucial problem, which seems to be very obstinate. A very large prize, indeed, awaits the processing specialist who is first able to resolve this impasse, either by inventing a new form of continuous quench-casting or by some totally different approach. □

## Differential function of major histocompatibility complex antigens in T-lymphocyte activation

Fritz H. Bach, Marilyn L. Bach & Paul M. Sondel

*The antigenic systems of the major histocompatibility complex can be subdivided into those which are serologically detectable and those which are detected in tests with mixed lymphocytes. The two systems have different roles in the activation of separate populations of T lymphocytes.*

FEW investigators attracted to the study of transplantation antigens controlled by the major histocompatibility complex (MHC) foresaw the multitude of fascinating biological phenomena related to genes of this region. MHC loci are involved not only in the control of strong transplantation antigens, but also in control of immune response, disease susceptibility, immune cell interactions, level of serum complement components and perhaps in developmental abnormalities; it seems that many of the genes determine cell surface structures. This review will deal largely with antigens controlled by the MHC, their genetic control and function in immunological reactions.

MHC associated antigens were originally detected by transplantation *in vivo*; the recognition of serologically defined antigens controlled by genes of that same genetic complex led to the question whether these antigens were themselves the strong histocompatibility (transplantation) antigens or genetic markers for them. Additional serological studies as well as the use of two *in vitro* models of cell-mediated immunity have provided evidence for the existence of cell surface antigens determined by MHC genes other than those controlling the initially described serologically defined antigens. The accumulated data suggest that different antigens of the MHC are separable on the basis not only of the recombinational events separating the genes coding for them, but also of different functional roles in terms of lymphocyte subpopulations that respond to them.

### Detection of MHC antigens

The two *in vitro* cellular models that have most extensively been used for the analysis of MHC associated antigens are the mixed leukocyte culture (MLC)<sup>1,2</sup> and cell-mediated lympholysis (CML)<sup>3-6</sup> assays (Fig. 1). In MLC tests, lymphocytes from one individual (the responder) are cultured for 4-7 d with stimulating lymphocytes from a second individual. To prevent their proliferation, stimulating cells are treated with mitomycin-C (ref. 7) or X rays<sup>8</sup> before they are added to responding cells. When the stimulating cells are from individuals whose MHC is different from that of the responder the untreated responder lymphocytes proliferate; this is detected by incorporation

of tritiated thymidine (<sup>3</sup>H-TdR) into the proliferating cells in the MLC assay. For CML assays, cytotoxic T lymphocytes (CTLs) are "generated" in mixed leukocyte cultures<sup>9-11</sup>. After incubation for several days, the responding cells are assayed as effector lymphocytes for their cytolytic activity as measured by their ability to lyse radioactively sodium chromate (<sup>51</sup>Cr) labelled target cells; if the target cells carry the same (or cross reactive) antigens as the stimulating (sensitising) cells in MLC, then the target cells are lysed<sup>12</sup>. The amount of <sup>51</sup>Cr released into the medium is a quantitative assay for lysis and is expressed as CML. Since the terminology in this field is complex and can be difficult to follow, terms and abbreviations used in this article are listed in Table 1.

On the basis of serological findings and the use of MLC and CML tests, it is possible to divide MHC determined cell surface antigens into at least three categories. First, the classical serologically defined antigens that are present on the surface of essentially all cells. We shall refer to these as the SD antigens. Second, some antigens which can be detected serologically are present only on restricted cell types, among them B lymphocytes, macrophages, epidermal cells and sperm<sup>13</sup>. These antigens are referred to as Ia (Ir-associated) in mouse and by other designations in man. Although it has not been conclusively established that these mouse and human antigenic systems are homologous we shall make that assumption and, since the human terminology has not been unified, refer to both as Ia. Third, there are the MHC antigens that, if different in two individuals, lead to an MLC proliferative response<sup>14,15</sup>. We shall refer to these as LD antigens<sup>15,16</sup>. Whereas genes determining the MHC SD antigens are genetically separable from those determining the Ia and LD antigens in both mouse and man, there may be some degree of identity between Ia and LD determinants.

It must be stressed that the designations SD, Ia and LD are simply terms we use to distinguish between MHC determinants that may have different biological roles. Since the terminology for these antigens and the loci coding for them are different in the several experimental species used for various studies, the terms allow simplified reference to and discussion of pertinent phenomenology related to what are presumably homologous systems in several species. In addition, in a single species several genetically separable loci coding for antigens all apparently subserving a single function can be conveniently referred to with a single

Fig. 1 Schematic representation of the MLC and CML tests. Cells differing for the major histocompatibility complex are mixed *in vitro*: for the MLC assay, proliferative activity is assayed after 4-5 d by studying incorporation of radioactive thymidine; for the CML assay, the initial responding cells are tested for their cytotoxic capacity against radioactively labelled target cells, the amount of radioactive label released from the target cells by the effector cells is expressed as % CML.

term. The terms should in no way imply that a function associated with LD cannot also be associated with SD; for example, that SD antigens cannot induce lymphocyte proliferation. On the premise that the broad biological principles discussed in this article are the same in mouse and man, we shall draw freely on data obtained in both species.

## Genetics of the MHC in mouse and man

The MHC in mouse, called *H-2*, has been divided into five regions<sup>13,17</sup>, K, I, S, G and D on the basis of marker loci for each region (Fig. 2). The K and D regions have as their marker loci *H-2K* and *H-2D*, that control the *H-2* SD antigens. The I region can be subdivided on the basis of different Ia determinants associated with each of three sub-regions: I-A, I-B and I-C<sup>13,14,17,18</sup>. Included in I-A are loci determining certain Ia antigens, an immune response (*Ir*) locus controlling the ability of an animal to respond immunologically to a variety of antigens, and the strongest *H-2* LD locus, that is differences for this locus lead to strong proliferative responses in MLC. Within this subregion the genes determining Ia antigens, LD determinants, and controlling immune response have not been genetically

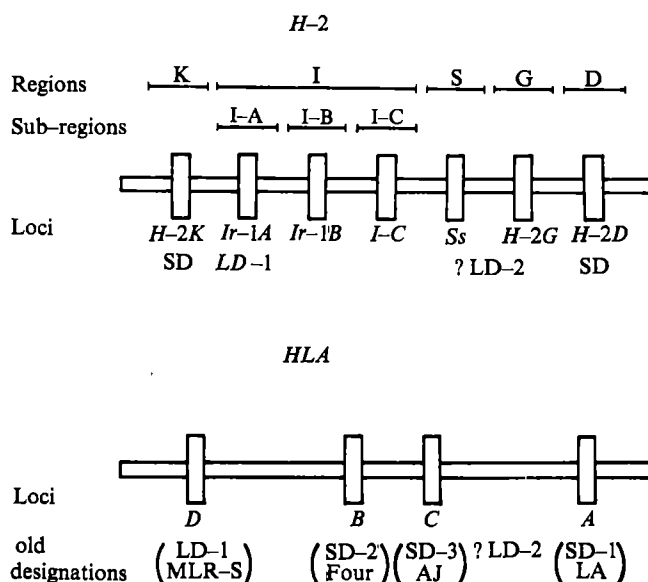

separated. Partial identity of *Ir* and Ia genes is suggested by the existence of a soluble factor that bears Ia antigen determinants and that is involved in regulation of the immune response<sup>19,20</sup>.

The human MHC, termed HLA (Fig. 2) has three different SD loci, *HLA-A*, *HLA-B* and *HLA-C* and one strong LD locus, *HLA-D*; a weak LD locus may exist between *HLA-A* and *HLA-C*. Van Leeuwen *et al.*<sup>21</sup> and more recently Winchester *et al.*<sup>22</sup> have demonstrated the existence of cell surface antigens determined by genes of the human MHC that at least in part have a similar tissue distribution to the mouse Ia antigens.

For convenience in further discussion, the word "locus" will be used to describe the genetic control of all antigens or determinants where it has not been shown that more than one cistron is involved. Two strains (individuals) designated "LD different" differ for the strong LD locus and are identical for the SD loci; those designated "SD different" differ for either the K and/or D regions in mouse or the SD loci in man but are identical for the strong LD

Fig. 2 Diagrammatic representation of the major histocompatibility complex in mouse and man. In mouse, the complex is divided into five regions with the I region further divided into three sub-regions. Marker loci for each of the sub-regions are shown. The strongest LD locus is in the I-A sub-region; a weaker LD locus may be present between *Ss* and *H-2D*. The *H-2D* and *H-2K* loci are the SD loci.

Table 1 Abbreviations and terms	
MHC	Major histocompatibility complex, <i>H-2</i> in mouse and <i>HLA</i> in man.
<i>Ir</i>	Immune response loci alleles which control the ability of an animal to respond to a variety of antigens.
Ia	The antigens controlled by the <i>H-2</i> I region in mouse that are primarily expressed on B lymphocytes, macrophages, epidermal cells and sperm. An apparently homologous antigenic system has been described in man.
MLC	Mixed leukocyte culture test; usually assayed by study of thymidine incorporation into stimulated lymphocytes.
LD	The MHC loci and antigens primarily responsible for inducing thymidine incorporation (cell proliferation) in MLC. The stronger of them are controlled by <i>HLA-D</i> in man and <i>LD-1</i> in mouse.
PHCs	Proliferating helper cells; the T lymphocyte subpopulation that is primarily responsive to MHC LD antigens. These T cells do not adhere well to allogeneic monolayers and carry the Ly-1 differentiation antigens.
CML	Cell-mediated lympholysis assay, assayed by studying release of <sup>51</sup> Cr from labelled target cells.
SD	The MHC loci and antigens (or genetic markers for the antigens) that serve as the primary targets for the cytotoxic T lymphocytes. These are the classical serologically defined antigens of <i>H-2K</i> and <i>H-2D</i> in mouse and <i>HLA-A</i> , <i>-B</i> and <i>-C</i> in man.
CTLs	Cytotoxic T lymphocytes active in the CML assay. These T cells adhere to allogeneic monolayers and carry the Ly-2 and Ly-3 differentiation antigens.

locus. This focuses on only the MHC LD and SD loci; other MHC loci may well be involved in the reactions discussed.

## Genetic control of MLC

In man, the *HLA-D* (*LD-1*) locus has the predominant role in inducing proliferation in MLC; differences for the SD loci do not, by themselves, lead to strong MLC activation (reviewed in refs 23 and 24). Cells of siblings that are *HLA-D* identical but differ for SD loci either do not stimulate each other at all or do only minimally<sup>25,26</sup>; this low stimulation may be due to SD antigenic differences themselves and/or to a weak LD locus between *HLA-A* and *HLA-C*. It is not established whether *HLA* SD antigens provide a significant additional proliferative stimulus in MLC in the presence of *HLA-D* disparity.

In mouse, a strong LD locus in the *H-2* I region is primarily responsible for proliferative events in MLC; differences for the *H-2* SD regions (K and/or D) given I region identity are also significantly stimulatory although to a lesser extent. These latter proliferative responses, as in man, may be caused by the SD antigens or by LD-type stimuli within the K and D regions (for example, there is evidence for an LD locus between S and D<sup>27</sup>). In mouse, apparently unlike man, there is a locus (*Mls*) alleles of which segregate independently of *H-2*, and differences at which lead to an MLC proliferative response<sup>28</sup>. Even in xenogeneic combinations, such as man-mouse, the same *H-2* regions that lead to an allogeneic MLC reaction provide the proliferative stimulus (K. F. Lindahl and F.H.B., in preparation).

## Genetic control of CML

Despite the finding that the MHC LD antigens are primarily responsible for activating the proliferative response in MLC, and that cytotoxic T lymphocytes (CTLs) active in CML are generated in MLC, the target antigens primarily recognised by CTLs are not LD. Rather the specific lytic effect of CTLs is directed at either the MHC SD antigens themselves or the phenotypic product of genes very closely linked to those determining the SD antigens<sup>29-33</sup>. This is, once again, true even in xenogeneic combinations<sup>34</sup>. We shall, for simplicity, refer to them as the SD antigens.

These findings are most elegantly demonstrated in "three-cell" experiments<sup>35,36</sup>, in which cells of one strain (individual) are simultaneously stimulated by mitomycin-C treated cells of two other strains, one differing from the responding cells by LD and the second differing by SD antigens (Table 2). In addition these data give evidence for "LD-SD collaboration". Cells of two LD different strains (AQR-B10.T(6R)) stimulate each other significantly in MLC but the LD stimulus by itself does not generate cytotoxic cells directed at the SD target. Two SD region different strains (AQR-B10.A) lead to a relatively weaker proliferative response (compared with that caused by I region LD differences) and highly significant cytotoxicity against B10.A<sup>37,38</sup>. The simultaneous presentation of LD and SD stimuli, however, leads to a markedly enhanced cytotoxic response against SD different target cells (LD-SD collaboration). The CML % is linearly related to the log of the number of CTLs; a difference from 21.8% to 40.4% thus represents much greater than a twofold difference in terms of lytic potential<sup>32</sup>. The LD-SD collaboration will be analysed in greater detail later (see Table 4). It should be pointed out, however, that whereas the stimulation of AQR cells by B10.T(6R) does not lead to CML directed at B10.A, relatively low level but highly significant CML directed at B10.T(6R) does result<sup>32,38</sup> (see also Table 4).

These results demonstrate clearly the LD-SD co-operation; that is the presence of an LD difference in the stimulating mixture markedly enhances the development

Table 2 LD-SD collaboration in a three-cell experiment

<sup>3</sup> H-TdR incorporated (c.p.m.) $\pm$ s.d.*	Target cell	%CML $\pm$ s.d.
10,842 $\pm$ 236 AQR + 6R <sub>m</sub>	B10.A	-1.2 $\pm$ 3.1
4,113 $\pm$ 190 AQR + B10.A <sub>m</sub>	B10.A	21.8 $\pm$ 2.1
8,292 $\pm$ 309 AQR + 6R <sub>m</sub> + B10.A <sub>m</sub>	B10.A	40.4 $\pm$ 2.8

\*The control culture AQR(AQR)<sub>m</sub> incorporated 2,926  $\pm$  254 c.p.m. <sup>3</sup>H-TdR.

The strain B10.T(6R) is abbreviated as 6R. The designations for the seven regions and subregions of *H-2* (K, I-A, I-B, I-C, S, G and D) for the strains are as follows: AQR, qkkddddd; 6R, qqqqq?d; B10.A, kkkddddd. As such, AQR and 6R are *H-2* SD identical but different by LD, and AQR and B10.A are K region different but identical for the rest of *H-2* (D. J. Schendel and F.H.B., unpublished data).

of cytotoxicity against the SD region target even though the LD stimulus by itself does not generate cytotoxic cells against that target. In contrast, the presence of the SD antigen does not enhance anti-LD (anti-I region) CML (see Table 4 and later discussion).

Experiments with human cells yield similar results with one exception: SD antigenic disparity "alone" (that is *HLA-D* identity) leads neither to a strong proliferative response nor to a detectable cytotoxic response<sup>25,29,30,36,39</sup> contrasting with the MLC and CML associated with SD region differences in mouse. The high magnitude proliferative and cytotoxic responses seen in LD plus SD disparate human MLCs would suggest that this difference is not due to insensitivity of the human method although the culture technique cannot be ruled out as the explanation. The discrepancy could be based on variation of human and mouse SD antigen presentation or recognition. Alternatively, it may be explained by the evolutionary generation of somewhat different arrangements of the genes of human and mouse MHCs (see Fig. 1). In mouse, the *H-2K* locus and loci of the I-A sub-region are very closely linked; recombinational events between them may in most cases result in the inclusion of some relatively weak LD loci in what we call the "SD region". In contrast the probably tenfold greater recombinational frequency between *HLA-B* and *HLA-D* may prevent such LD loci from being included in the SD segment of most human recombinant chromosomes, thereby allowing a more complete genetic separation of LD and SD antigens in human recombinants.

## Cellular recognition of MHC antigens

The cells responding in MLC and CML are primarily T cells. On the basis of evidence that functionally different subpopulations of T cells exist<sup>40</sup>, we suggested in 1972<sup>41</sup> that the LD-SD dichotomy might be explained at the cellular level by the existence of two separate subpopulations of T cells, one responding primarily to LD (the proliferating helper cell—PHC) and another responding to SD (the cytotoxic T lymphocyte—CTL). Results of experiments using cellular immunoadsorbents<sup>42</sup> (monolayers of allogeneic adherent cells) were consistent with the existence of two separate populations of T lymphocytes, one responding to LD by proliferation and not adhering to an allogeneic monolayer; the other, the CTLs adhering to the monolayer. These two cell populations can be separated before sensitisation in MLC. An example of such an experiment is shown in Fig. 3. Cells of individual A are adsorbed on to either an A, B or C monolayer; 1 h later the non-adherent cells are removed from the monolayer and stimulated with cells of individual B and tested on B target cells. The level of cytotoxicity generated against B when the non-adherent A cells recovered from the B monolayer are stimulated with B<sub>m</sub> is minimal compared with similarly stimulated non-adherent cells from the A or C monolayers. In 12 experiments<sup>43</sup> the average reduction in cytotoxic activity

(lytic units or potency) of non-adherent lymphocytes after pre-adsorption on allogeneic monolayers was 70% whereas only a 12% reduction in  $^3\text{H}$ -TdR incorporation measured in MLC was observed. The adsorption experiments are consistent with the finding that the CTLs divide (ref. 43 and B. J. Alter and F.H.B., unpublished) (incorporate  $^3\text{H}$ -TdR), although they seem to contribute only a relatively small percentage to the total  $^3\text{H}$ -TdR incorporated in a normal MLC—most is incorporated by the PHCs<sup>41,42</sup>.

The concept of two cell populations responding to LD and SD antigens was strengthened by the findings of Cantor and Boyse<sup>44,45</sup> using antisera against Ly cell surface antigens. These antigens are T-cell differentiation markers controlled by three loci, *Ly-1*, *Ly-2* and *Ly-3*. It seems

Fig. 3 Non-sensitised reciprocal adsorption. Cells of individual A (listed before the /) are adsorbed on either an autologous, A, monolayer or on allogeneic monolayers from individuals B or C (listed immediately after the /). The non-adherent cells from the monolayer are then stimulated with mitomycin-C treated cells from individual B (designated B<sub>m</sub>), and assayed 5 d later for their ability to lyse B target cells. The marked reduction in cytotoxic activity following adsorption on the B monolayer, compared with the A or the C monolayer, is shown with no significant decrease in the proliferative activity. The reciprocal experiment stimulating the non-adherent cells with mitomycin-C treated cells of individual C and testing on C target cells in CML gave qualitatively similar results. (From K. S. Zier and F.H.B., unpublished.)

that LD responsive PHCs are *Ly-1*+ and do not mediate cytotoxicity; *Ly-2,3*+ cells divide and become CTLs. Support for the dual T-cell concept has also come from studies of Wagner *et al.*<sup>46,47</sup>.

## Responses to LD and SD *in vivo*

The functional distinction of LD and SD antigens has been supported largely by experiments involving discrimination of cellular immune recognition *in vitro*. Of great importance is the integration of both antigenic and cellular distinctions into the overall process of allograft reactions *in vivo*. The importance of LD and SD antigens has been studied *in vivo* using both graft versus host and graft rejection assays.

Essentially similar results have been obtained in a number of graft versus host (GvH) test systems including splenomegaly, lymph node enlargement, or increased radioactive IUdR incorporation into spleen or lymph node cells following injection of histoincompatible immunocompetent cells. Results closely parallel those found in the MLC; that is

LD differences are very potent at eliciting GvH reactions, the SD differences are relatively weak in this regard<sup>48-50</sup>. Representative results from one experiment performed by Elkins *et al.*<sup>50</sup> are given in Table 3. Most important are the findings that the LD differences (I+S) are quite strong in eliciting the response; two strains that differ by only the K region or the D region plus I-B, I-C, S and G do not elicit a significant response in this test system<sup>49</sup>.

In man, the survival of transplanted tissue in non-presensitised individuals is prolonged by identity for either LD or SD antigens<sup>51-53</sup>. Of the two types of MHC determinants, preliminary data in man suggest that identity for LD has greater predictive significance for the length of graft survival, at least with respect to skin and kidney grafts<sup>51</sup>; but this distinction requires further study.

One important facet of the response to allogeneic tissue *in vivo* is not usually detected by routine MLC and CML testing *in vitro*: the influence of alloantibody. Human renal graft recipients immunised with multiple whole blood transfusions often produce cytotoxic alloantibody. The presence of antibody directed against donor tissue SD antigens induces accelerated and sometimes hyperacute

Table 3a Response of B10.T(6R) thymocytes to I+S region difference

Host strain	% activity recovered in spleen*	H-2 region difference
(AQR × 6R) F <sub>1</sub>	0.63 (0.44-0.73)	I+S
B10.A	1.12 (1.10-1.44)	K+I+S
B10.T(6R)	0.03 (0.02-0.03)	None

\*Median (range)

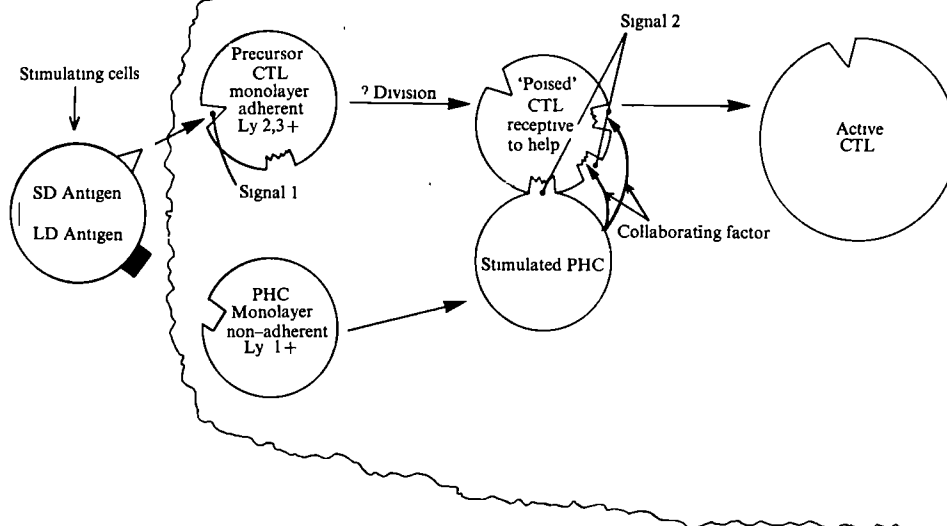

Table 3b Response of B10.A thymocytes to various regions of the H-2 complex

Host strain	Number of hosts	% activity recovered in spleen*	H-2 region difference
AQR	6	0.03 (0.01-0.04)	K
B10.A(4R)	4	0.02 (0.02-0.02)	I-B, I-C, S, G, D
B10	6	0.36 (0.17-0.47)	Complete
B10.A	5	0.02 (0.01-0.03)	None

\*Median (range).

The response of thymocytes to various regions of the H-2 complex is assayed by studying the incorporation of radioactive iodouracil-deoxyriboside (IUdR) into the spleens of recipient animals. The % activity recovered in spleen is in relation to the entire radioactivity injected. Control values usually range between 0.02 and 0.05%; a value of 0.36% is highly significant. (After Elkins *et al.*<sup>50</sup>.)

rejection<sup>54</sup>. Other transfused patients who do not have antibody directed at donor SD antigens more readily accept and retain allografts than non-transfused transplant recipients. van Rood has suggested this increased graft survival after many transfusions results from immunisation to LD determinants and subsequent production of an antibody that enhances graft survival (results presented at the annual meeting of the AASCT, 1975). Such enhancement has been demonstrated in mouse by passive transfer of anti-Ia antisera that prolong graft survival even when administered in  $\mu\text{g kg}^{-1}$  quantities; anti-SD antibody did not enhance graft survival<sup>55</sup>. The apparently differential role of

**Fig. 4** Primary response. A stimulating cell carrying both an SD antigen(s) and an LD antigen(s) will evoke separate responses in two T-cell subpopulations in a manner similar to that depicted in the original cellular model proposed to explain the LD-SD dichotomy<sup>41</sup>. We can refer to the recognition of the SD antigen by the precursor CTL as signal 1. This cell is monolayer adherent and Ly-2,3+. It seems, on the basis of results shown in Table 4, that when the LD and SD stimuli are added at different times after initiation of culture, the SD antigens initiate a step in differentiation which may be independent of LD. This differentiation step results in a "poised" CTL which is receptive to help. A separate cell population of T lymphocytes, the proliferating helper cells, respond to LD antigens. This cell is monolayer non-adherent and Ly-1+. The help given by the PHC to the poised CTL might be delivered either by cell-cell contact between the PHC and the poised CTL or by a "collaborating factor" (secreted from the stimulated PHC) to which the poised CTL can respond. This is an obvious analogy to the model for T-B cell collaboration. It is a purely gratuitous assumption that the receptor on the CTL that recognises the collaborating factor is present in an effectively increased number on the cell as compared with the precursor CTL. Many alternative mechanisms may account for the fact that the poised CTL is more receptive to help than the precursor CTL. The direct contact between the stimulated PHC and the poised CTL or the collaborating factor would provide signal 2 to the CTL and lead to further differentiation to an active CTL. To what degree a CTL receiving only signal 1 can become cytotoxic and the other aspects of this model are discussed in this article. We have recently elaborated on this model to include the "secondary" responses of lymphocytes in culture<sup>58</sup>.

antibody directed at Ia (?LD) and SD molecules once again is consistent with a dichotomy of function.

### An attempt at synthesis

We have discussed above data supporting the contention that LD and SD antigens are functionally distinct and that two separable populations of T lymphocytes respond to these antigens. We shall now attempt to expand on our previous model to explain how LD and SD antigens and their respective responding lymphocyte populations interact in the generation of a specific cytotoxic response. The elaboration is based on the Bretscher-Cohn model for B-cell activation<sup>56</sup> and is in general agreement with Crichton and Lafferty<sup>57</sup>. It would suggest that the CTL receives two signals for activation: "signal one", the SD antigen, and "signal two" given by the PHC after it has been stimulated by LD. It is quite likely that many stimuli will, either through the PHC or by acting directly on the CTL, be able to provide signal two. This model is illustrated in Fig. 4. In this context the LD-SD dichotomy can be summarised as follows. (1) The SD antigens function as the prime CTL activating determinants and as targets for these cells. The weak proliferative response stimulated by SD region differences in mouse may reflect CTL division or stimulation of an SD reactive PHC population. Alternatively the proliferative response is due to PHCs responding to LD determinants included in the "SD region difference". (2) A strong MHC LD locus, separable from the SD loci, is primarily responsible for stimulating the strong proliferative response in MLC and presumably for inducing the PHC-CTL helper effect. One or more weaker MHC LD loci probably exist. Weak but significant cytotoxicity is often associated with I region differences; it is not established

whether this is directed against LD as opposed to other I region antigens. (3) There is very substantial and clear evidence for LD-SD collaboration based on both genetic and cellular studies. The presence of an LD stimulus in the sensitising MLC markedly enhances the development of cytotoxicity aimed at the SD region targets unless maximum CML is already present (M. B. Widmer, F.H.B., H. R. McDonald and J. C. Cerrotini, unpublished) *in vitro* due to the presence of a strong signal 2 such as may be provided by heterologous serum or conditioned medium, even though stimulation by LD alone does not generate cytotoxicity against the SD target. It is not known whether the LD helper effect is essential and the CML generated in SD region different strains is due to an LD-like stimulus determined by gene(s) in that region, or that LD simply influences the quantitative amount of CML induced by SD alone. The suggestion that the SD antigens actually initiate (signal 1) a differentiative response that is expanded, or allowed to differentiate further, by the presence of cells responding to the LD stimulus (signal 2) is based on kinetic experiments in which SD and LD stimuli are added to responding cell populations at different times. The basic findings<sup>58</sup>, which look quite similar to those on T-B cell collaboration, are illustrated in Table 4. If the SD different stimulus (in a "three-cell" protocol) is added at time zero and the LD stimulus is delayed for 24 h, the CML against B10.A target cells is in fact increased, although the kinetics of the development of the cytotoxic response aimed at the SD antigens may differ (see day 5). Adding the 6R<sub>x</sub> cells 48 h after initiation of the AQR(B10.A)<sub>UV</sub> culture still results in 48.7±4.8% CML on B10.A target cells. In the reciprocal direction, delay in adding the SD different cells, after adding the LD different cells on day zero, results in a similar delay in the development of CML. We have

discussed this in detail elsewhere<sup>38</sup>. Most important, the presence of the SD stimulus does not seem to potentiate "anti-LD" CML. This is in contrast to the potentiation of anti-SD CML by an LD stimulus, and further supports the LD-SD dichotomy.

Two findings might seem to contradict the need for signal 2 in the generation of CTLs. First, that Ly-2,3+ lymphocytes alone can respond to an entire MHC difference and become CTLs<sup>49</sup>. This apparent circumvention of the PHC role could be explained by several models. First, a relatively weak signal 2 can be given directly to the CTL by mechanisms other than PHC collaboration either by the SD antigens themselves or some other stimulus. Second, the Ly-2,3+ cells may be a heterogeneous population, a portion of which can respond to the LD antigens and thereby provide the helper effect to allow CTLs within that population to develop. This is consistent with the finding in those same studies that an Ly-2,3+ population depleted of Ly-1+ cells still shows a highly significant proliferative response to strains differing for only the I and S regions (that is, LD different-SD identical strains) without showing CML activity<sup>45</sup>. The lack of cytotoxicity in this situation suggests that the proliferation seen is not due to division of CTLs. Third, the Ly-1+ cells that proliferate in response to LD (proliferating "helper" cells) may not be required for the induction of CTLs but may simply expand an ongoing response and may be functionally distinct from Ly-2,3+ LD reactive cells. Finally, it may be that PHCs in the stimulating cell population respond to LD antigens on the responding cells and provide the helper effect to the responding CTLs. If help is provided by means of a factor, the observation that mitomycin-C treated cells do produce factors is important<sup>50</sup>.

The second apparent contradiction is the finding that an SD region difference alone can stimulate both proliferative and CML responses in mouse. Ultraviolet irradiation of stimulating cells abrogates their ability to evoke a proliferative MLC response thus appearing to ablate LD expression; the SD antigens on ultraviolet-treated cells can still be detected serologically<sup>60</sup>. In Table 4 the SD region different stimulating cells are treated with ultraviolet irradiation rather than mitomycin-C<sup>38</sup>. In these circumstances the cells evoke minimal if any proliferative or cytotoxic response. The addition of an LD stimulus to the sensitising mixture however still leads to a very marked cytotoxic response against the SD different target cells.

The three-cell experiments with ultraviolet-treated stimulating cells show that an SD stimulus that is effective at activating CTLs is not capable of strongly stimulating the PHC and does not by itself lead to as great a cytotoxic reaction as in the presence of LD. At least four mechanisms could be invoked to explain the difference between the mitomycin-C treated (see Table 2) and ultraviolet-treated SD region disparate stimulating cells. First, the same determinant on the SD molecule may be responsible for activating the PHC and CTL but the two cell populations have different requirements for activation (possibly due to molecularly different recognition molecules). Treatment with ultraviolet light leaves a cell still capable of activating CTLs but not PHCs. For example, the cell surface density of SD antigens may be reduced by ultraviolet treatment making the SD stimulus ineffective at stimulating PHCs or providing signal 2 directly to the CTL. Second, cellular contact initiated by recognition of surface SD antigen might allow a cell membrane interaction (possibly unrelated to antigen recognition) to provide a weak substitute for signal 2. Ultraviolet-treated stimulating cells provide the SD stimulus (signal 1) but are unable to provide the substitute signal 2 and therefore require an additional generation of signal 2 provided by the LD stimulus by way of PHCs. Third, an ultraviolet-sensitive part of the SD molecule different from that triggering the CTL may activate the PHC. This is similar to our initial analogy of a carrier-hapten system to the LD-SD problem<sup>15,35</sup> and the reiteration of that model applied to the SD antigen<sup>65</sup>. Fourth, there may be LD-type loci in the K region separable from the SD loci<sup>32</sup>. Conceptually, in terms of phenotypic expression, the third and fourth models both suggest that the LD and SD antigens are determined by genetically separate sites; the question whether the LD and SD stimuli are determined by separate genes or separate subclonogenic segments is not terribly important in this context.

## Mutants of H-2

The studies that first led to the definition of H-2 LD loci<sup>15,16,62</sup> were done using a mouse strain, discovered by Bailey, that carries a spontaneous mutation in *H-2* to the left of *Ss*<sup>63</sup>. The phenotypic expression of the mutation is reciprocal skin graft rejection between the parental strain, C57BL/6, and the mutant, H(2l), in spite of apparent serological identity of cells of the two strains. More recent

		6R	13.9 $\pm$ 1.8	14.9 $\pm$ 4.2
		B10.A	12.1 $\pm$ 1.6	40.3 $\pm$ 7.1
AQR+AQR <sub>x</sub>	975 $\pm$ 34	AQR	-2.1 $\pm$ 0.9	-11.1 $\pm$ 2.7
		6R	-1.5 $\pm$ 1.7	-12.2 $\pm$ 3.6
		B10.A	—	8.3 $\pm$ 3.0

The control effector combination, AQR+AQR<sub>x</sub>, gives 8.3  $\pm$  3% CML on the B10.A target cells. It is thus difficult to know whether there is any significant killing on B10.A target cells when AQR cells are stimulated with B10.A<sub>UV</sub>. A 24-h delay in adding the B10.A<sub>UV</sub> cells results in a level of cytotoxicity on B10.A target cells on day 6 not significantly different from that found on day 5 when the LD and SD stimuli are added together at time zero. (D. J. Schendel and F. H. B., *Eur. J. Immun.*, in the press.)

studies suggest that a serological difference may exist<sup>64,65</sup>. Consistent with this possibility are recent findings that the SD antigenic products of BL/6 and H(zl) differ by peptide mapping (J. L. Brown and S. Nathanson, personal communication). In MLC and CML, both a proliferative response and a very marked cytotoxic reaction were seen reciprocally (see Table 5); the magnitude of the cytotoxic response between cells of the parental and mutant strain is comparable to that observed in the responses between mouse strains known to differ for both LD and SD antigens, and significantly greater than that observed between strains differing only for an SD region. The existence of both the MLC proliferative response and CML cytotoxicity related to these mutants has been extensively discussed<sup>24,62,64,65</sup>.

It is possible that the spontaneous mutants carry "point mutations" that affect only a single phenotypic product of the MHC, the SD molecule. By this assumption one must explain why CML equal to that found in LD+SD different strains is present in the C57BL/6-H(zl) combination. Two considerations may be helpful. The basis on which these mutants were found, that is relatively rapid skin graft rejection, may have selected for highly immunogenic SD antigens that can alone account for these findings. In addition, proliferative responses between C57BL/6 and the mutants are on the average weaker than those seen in H-2 disparate strains. This would again be consistent with a highly immunogenic SD difference that by itself induces a sufficient helper proliferative response (or in some other way gives signal 2) to allow strong CML to develop. We do not know how great the helper response must be for CML to develop, and a relatively low response may in this case be enough. The discussion above of the apparent circumvention of LD-SD collaboration in SD region different strains alone is also applicable in this instance.

The spontaneous derivation of H(zl) does not prove that the mutant differs only for an amino acid substitution in the SD gene product. Subsequent skin graft screening of C57BL/6 animals revealed a surprisingly large proportion (more than 1%) of independently derived H-2 mutants<sup>78</sup> suggesting a somewhat non-conventional mutation mechanism. Because F<sub>1</sub> hybrids of any two of these H-2 mutants reject parental skin grafts, it seems that at least one common genetic determinant was altered in each independent mutational event; however, these "complementation" studies do not exclude the possibility that the mutational event also resulted in changes of other MHC controlled determinants. It does not seem unreasonable to hypothesise that a spontaneous mutation would affect the phenotypic expression of more than a single molecule. Several mechanisms could be suggested.

First, it may be that spontaneous mutation affects only one molecule in terms of an amino acid substitution, for instance the SD antigen. That SD antigenic molecule may interact in a physically intimate manner with the LD antigen so that a change in the SD antigenic molecule may result in a change in the expression of the LD antigen. We have recently discussed possible LD-SD epistasis in MLC reactions<sup>66</sup>. Arguing against this possibility is the lack of any such finding in mouse strains carrying recombinant chromosomes. Second, it may be that these mutant strains were generated by the effects of complex mutation events. By this model we predict that the LD antigens, of these mutant strains, when isolated, will have one (or more) amino acid substitution(s) from the parental LD, as does the SD molecule in the case of H(zl). Third, it may be that mutations of LD and/or SD products are not infrequent and are, in fact, carried by many inbred lines. Let us hypothesise that rapid skin graft rejection between the two strains is dependent on differences for both LD and SD-type antigens. The mutants mentioned here were identified by skin grafting only; the parental mice were not routinely screened for mutations in LD alone, as detected in MLC,

Table 5 MLC and CML studies in the H-2 mutant H(zl)

(From M. Widmer, unpublished.)

or for mutations in SD alone, as detected in "three-cell" CML protocols. It is thus possible that some of the parental BL/6 lines may have been carrying either an LD or an SD mutation that was not detected by skin grafting. Subsequent mutation could then yield "spontaneous" mutants identified by skin grafting because they now differed from the original parental line for both LD and SD antigens.

Any one of these explanations as well as other models would explain the complex phenotypic expression in these mutants; the biochemical isolation and characterisation of LD and SD phenotypic products will be of tremendous benefit in understanding the LD-SD dichotomy, particularly with respect to these mutants. Clearly, the LD-SD model is an oversimplification of the genetics of histocompatibility antigens within the MHC; given our present state of knowledge, the model of a functional dichotomy of LD and SD antigens is consistent with all data collected so far, including these mutants, and serves as an heuristically valuable model.

## Questions of genotypic identity

Responses of T lymphocyte subpopulations have been ascribed to antigens associated with a given H-2 or HLA region. In considering the genetic relationship of these antigens and the other functions ascribed to the same MHC (sub)regions, three basic questions of identity arise: (1) are the target antigens recognised by the CTLs identical to the SD molecules or, even more specifically, the determinants on the SD molecules that are recognised by antibody? (2) Are the LD antigens identical to the Ia antigens? (3) Are the LD antigens identical to the products of the I region locus<sup>48,61</sup> causing skin graft rejection?

We and others have in the past discussed whether one can equate SD antigens with CTL target determinants<sup>24,62,67,68</sup>. Data presented in Table 6 demonstrate that human CTLs sensitised to lyse cells from the stimulating cell donor can also lyse target cells from a third party not sharing any serologically detectable cross reactivities with the stimulating cell donor. Experiments using a CML "blocking" technique have demonstrated that this cross killing is specific<sup>68</sup>, cytotoxicity of target cells from a third party results from CTL recognition of shared antigens on the initial stimulating cells and the target cells. Family studies have demonstrated<sup>69</sup> that these serologically undetected shared antigens are genetically controlled within the MHC.

Table 6 CML cross killing

CTLs	W	Target X	Y	Z
ZW <sub>m</sub>	62.5±2.8 (25)	55.9±3.2 (10)	38.5±2.7 (2)	1.7±3.9
ZX <sub>m</sub>	48.4±4.3 <sup>a</sup> (10) <sup>b</sup>	67.6±6.2 (25)	29.3±3.5 (1)	0.3±3.1
ZY <sub>m</sub>	40.7±3.8 (6)	28.6±2.3 (2)	58.9±3.4 (25)	-1.6±3.2
Z--	0.4±1.7	-3.1±2.3	-1.7±2.5	—

CTLs from the indicated mixed leukocyte cultures as well as unstimulated cells from Z, were tested on target cells from individuals W, X, Y and Z. No cross reacting or shared antigens were detected serologically among individuals W, X and Y. Typing results are as follows: W = (1, 8); X = (2, 12); Y = (10, 7, 27); Z = (10, 11, W15, W16). (In other experiments similar results were obtained with all four antigens of HLA-A and HLA-B defined in every individual.) Percentage cytotoxicity by  $25 \times 10^4$  CTLs on  $1 \times 10^4$  target cells are shown. Potency values in parentheses represent the number of specifically sensitised cells from Z that cause the same percentage cytotoxicity as  $25 \times 10^6$  of the CTLs being examined. Potency values were interpolated from a log-linear graph of several specific CTL concentrations against percentage cytotoxicity. Control values for each target (<sup>51</sup>Cr c.p.m.): W, S.R. =  $211 \pm 20$ , Max. =  $1,913 \pm 22$ ; X, S.R. =  $206 \pm 16$ ; Max. =  $1,089 \pm 46$ ; Y, S.R. =  $246 \pm 30$ ; Max. =  $1,597 \pm 50$ ; Z, S.R. =  $322 \pm 42$ , Max. =  $1,714 \pm 72$ . (From ref. 68.)

These data could thus be interpreted to suggest that the target for the CTLs is determined by MHC genes that are different from those determining the SD antigens, a suggestion made in our initial study with the C57BL/6-H(zl) mutant combination<sup>62</sup>. Alternatively, the cytotoxic target antigen may be the SD molecule itself, that is the same molecular determinant that evokes antibody production is recognised by CTLs; the antibody-producing B cell and the CTL, however, recognise the same determinant with different specificity, possibly by molecularly distinct receptor molecules, as suggested recently<sup>67</sup>. It is also possible that the CTLs recognise a different portion of the SD molecule from that recognised by B-cell produced antibody. The recent findings in mouse that CTLs may react with not only the private but also the public antigens of H-2 SD molecules may provide an explanation<sup>70</sup>; in man it is unlikely that antisera detecting public HLA SD antigens are frequently used. There is direct evidence that the CML targets are not the SD molecules<sup>71,72</sup>.

Evidence suggesting at least partial identity of Ia and LD determinants<sup>73</sup> demonstrated that anti-Ia antisera blocked the stimulating determinants in an MLC<sup>74</sup>. These findings can be used to argue that LD and Ia are, at least in part, identical; the ability of many different antibodies to block MLC reactions, however, prevents the firm acceptance of this last conclusion. In human studies, it has been noted by van Rood and his colleagues that there seem to be exceptions to the reaction patterns of the anti-human Ia antisera and the presumed LD determinants carried by those cells<sup>75</sup>. Even if LD antigens can be so defined, we would stress the difficulties of equating Ia antigens (detected by antibody) with LD antigens (detected by T cell reactivity in MLC). This caution is emphasised by the results we have discussed above in considering whether the antigen recognised by CTLs is the same SD antigen detected by alloantisera. In fact, there is no critical evidence that LD "determinants" are expressed on the cell surface.

A locus in the I region leads to skin graft rejection<sup>48,61</sup>. It might be reasonably argued that this locus is identical with the LD locus. One would then have to explain why LD-like differences in other parts of the H-2 complex are not associated with skin graft rejection. At least two possible explanations exist. It may be that I-A sub-region LD antigens collaborate with other I-A determined antigens (perhaps Ia) that are the targets for the CTLs; no such targets may exist in association with LD antigens in other regions. Alternatively, the LD antigens are the targets for the rejection response; the reason why skin graft rejection

may only be associated with LD differences in the I-A subregion is because these are the strongest LD differences of H-2. A threshold level of incompatibility may be needed before skin graft rejection will proceed.

## Summary

We have emphasised the functional dichotomy of MHC LD and SD antigens as well as the differences in cellular responses to these antigens. Perhaps in so doing we have failed to stress adequately the similarities that exist. But while the similarities (for example skin graft rejection associated with both K and I region differences) are so very clear, the differences have best allowed our progressive understanding of MHC induced cellular responses from the perspective stressed in this article. Of greatest importance to our understanding of these transplantation antigens are the potentially differential roles for the LD and SD antigens in the complex series of events that are collectively referred to as the "allograft reaction". It has been suggested that these differences may be "merely quantitative"<sup>61</sup>. This possibility has been discussed repeatedly in our previous reports on the distinction of LD and SD. In fact, the great bulk of biological phenomena can be reduced to quantitative differences. It would seem to us that sufficient evidence for such differential activity exists to make the LD-SD dichotomy model an heuristically valuable one for purposes of designing future experiments. We have discussed the clinical relevance of this model elsewhere<sup>23</sup>.

Many authors have speculated<sup>41,76,77</sup>, and evidence has been gathered<sup>19,20</sup> to suggest, that cell surface antigens associated with the MHC are important in developmental and other cell interactions. Some studies have directly addressed the question of the need for MHC compatibility to allow cell interaction to proceed optimally. It thus seems most appropriate that the genetic complex with which we are dealing has been termed the major histocompatibility complex; allowing for the literal interpretation of this term this may be the genetic region that by its influence on "tissue compatibility" may control critical cellular interactions in addition to those observed in allograft reactions. It is the simple good fortune for those whose attention was focused on this complex by transplantation problems to find themselves with a panorama of biological phenomena that require extensive experimental probing and integration, hopefully ultimately leading to an understanding of the MHC in a broader context than has to date been possible.

We thank Dr Seymour Abrahamson for valuable comments and our colleagues at the Immunobiology Research Center for stimulating discussions and critical review of the manuscript. # Two origins of replication in composite R plasmid DNA

Daniel Perlman & Robert H. Rownd

Laboratory of Molecular Biology and Department of Biochemistry, University of Wisconsin, Madison, Wisconsin 53706

*Electron microscopic examination of a composite R plasmid made up of an RTF component and an r-determinants component shows that replication may originate from either the RTF origin or the r-determinants origin of replication.*

MANY of the drug resistance plasmids (R plasmids) of the Enterobacteriaceae are composite structures consisting of two distinguishable components: a resistance transfer factor (RTF) which mediates the transfer of these plasmids during bacterial mating and an r-determinants component which harbours most of the drug resistance genes of the plasmid<sup>1-3</sup>. Each of these components is capable of autonomous replication in certain host strains of bacteria; that is, each is a "replicon"<sup>4-6</sup>. In most genera of the Enterobacteriaceae the RTF and r-determinants components are united to form the composite R plasmid structure<sup>1,2,4,6-8</sup>. This is also true in *Proteus mirabilis* when this host strain is cultured in drug-free medium<sup>7,9,10</sup>. When *P. mirabilis* is cultured in medium containing any of the drugs to which the r-determinants confer resistance, R plasmids are formed

which consist of a single copy of the RTF and multiple, tandem copies of the r-determinants component (poly-r-determinant R plasmids)<sup>2,5-7,9,10</sup>. Autonomous poly-r-determinants consisting of multiple copies of the r-determinants component are also formed<sup>9</sup>. Since both the RTF and the r-determinants component must contain an origin at which replication is initiated, the replication of R plasmids in *P. mirabilis* provides a model system for studying the replication of chromosomes containing multiple origins of replication. Here we show that either of the two origins of a composite R plasmid can be used for the initiation of R plasmid replication.

We have previously shown that there is a substantial increase in the fraction of replicating R plasmid DNA in *P. mirabilis* cells as a consequence of decreasing the rate of DNA chain elongation by limiting the concentration of DNA precursors<sup>10,11</sup>. Using this technique, three experiments were carried out to isolate replicating molecules of R plasmid NR1 DNA from *P. mirabilis*. In the cell culture conditions used, the R plasmid DNA exists as the undissociated composite structure (circular contour length of 37  $\mu$ m; molecular weight  $63 \times 10^6$ ) which consists of a single copy of the RTF (29  $\mu$ m; molecular weight  $49 \times 10^6$ ) and a

single copy of the r-determinants component ( $8.3 \mu\text{m}$ ; molecular weight  $14 \times 10^6$ )<sup>7,9-11</sup>. In two of the experiments thymine limitation was used to increase the fraction of replicating R plasmid DNA; in the third experiment treatment of the cells with hydroxyurea was used<sup>11</sup>. Fractionated R plasmid DNA was spread for electron microscopy at pH 10.7 so that approximately 20 small denaturation sites

**Fig. 1** Two examples of replicating molecules of composite R plasmid NR1 DNA. The two arrows indicate the two branch points (replication forks) of the replicating molecules. These two replicating molecules were isolated from R<sup>+</sup> *P. mirabilis* cells after addition of hydroxyurea to the growth medium. One molecule has initiated replication in the RTF component (A) and the other in the r-determinants component (B) of the composite R plasmid DNA. These molecules are designated as H-A and H-B in Fig. 2.

would be present in the R plasmid DNA<sup>12</sup>. We could thus compare the distribution of denaturation sites in the replicating molecules with the denaturation map of composite NR1 DNA. This made possible the orientation of the replicating molecules in a unique manner. The orientation of the replicating molecules was greatly facilitated by locating the  $8\text{-}\mu\text{m}$  r-determinants region which has very few denaturation sites when the DNA is spread for electron microscopy at pH 10.7 (ref. 12).

The replicating NR1 DNA molecules observed in the electron microscope were double-branched ( $\theta$ -type) circular structures when, as will be discussed subsequently, either the RTF origin (Fig. 1A) or the r-determinants origin (Fig. 1B) was used for the initiation of replication. The replicated regions (daughter branches) of the molecules were found to have equal contour lengths. Although

approximately 5% of the molecules observed in the electron microscope contained branch points (replication forks), only about one-fourth of these was suitable for detailed analysis. The criteria for choosing replicating molecules for mapping were as follows: (1) at least 10, and as many as 20, denaturation sites in each molecule were preferred for the most accurate alignment of the molecule with the NR1 DNA denaturation map; (2) the locations of the two replication branch points were clear and unambiguous; (3) there was no ambiguity in following the contour of the molecules throughout their entire length.

In Fig. 2 the distribution of denaturation sites and the replication branch positions in aligned molecules of replicating R plasmid DNA are superimposed on the composite NR1 DNA denaturation map. For convenience of presentation, the circular NR1 DNA molecules are represented by a linear denaturation map. The r-determinants component is located to the left side of the map (0.0–0.23) and the RTF component to the right side (0.23–1.0)<sup>12</sup>. Replicating molecules from the two thymine limitation experiments and the hydroxyurea experiment are designated T1, T2, and H, respectively. The weight-average histogram of the distribution of denaturation sites in all of the replicating molecules shown in Fig. 2 is presented in Fig. 3a. This histogram agrees well with the weight-average histogram (denaturation map) previously determined for non-replicating NR1 DNA molecules<sup>12</sup> (Fig. 3b).

The extent of replication and the branch positions of replicating R plasmid molecules are designated by arrows in Fig. 2. The positions of the replication branches are consistent with two different origins at which replication of the composite R plasmid DNA can be initiated. One is located in the r-determinants component at a position of 0.14 on the denaturation map. The other is located in the RTF component at a position of 0.80 on the denaturation map. The replicating molecules with the shortest replication branches were consistent with only these two origins and helped to localise their positions on the map.

Replicating molecules isolated from the same culture of cells were found to have initiated replication at either of these two origins of replication. In the case of either origin, replication could be either bidirectional or unidirectional in either sense. The replication branch points were usually not symmetrically arranged about either origin of replication. Replicating molecules have not been observed in which both origins were used simultaneously (that is, with four branch points). Such molecules may, however, be much more likely to fragment during isolation and handling of the DNA which would diminish their proportion in the population of replicating molecules.

A single replicating molecule has been observed by chance in an exponential culture which had not been subjected to substrate limitation. The replication of this molecule (designated as + in Fig. 2b) was initiated at the RTF origin and replication was bidirectional.

In many replicating molecules the branch point to the left of the r-determinants origin and the branch point to the right of the RTF origin tend to cluster around the position 0.95–1.00 on the denaturation map, suggesting that this position could be a terminus of replication. For several reasons it seems unlikely that this position is a third origin of replication. First, the positions of the two branch points of all of the replicating molecules which were analysed are consistent with either the r-determinants origin or the RTF origin. Second, none of the molecules with a small extent of replication (less than 15%) was consistent with an origin at 0.95–1.00. The existence of a terminus of replication at 0.95–1.00 could explain the asymmetry in the distribution of the replication branch points about the two origins since the arrival of one of the replication forks at the terminus would interrupt replication in that direction.

**Fig. 2** Denaturation sites and replication branch positions in aligned molecules of replicating R plasmid NR1 DNA superimposed on the composite NR1 DNA denaturation map. A thymine auxotroph of *P. mirabilis* harbouring the composite R plasmid NR1 was cultured in drug-free M9 minimal medium containing 0.06% casamino acids and other supplements<sup>11</sup>. In two of the experiments (T1 and T2) exponential phase cells were filtered, washed, and resuspended in similar medium containing a limiting concentration of thymine ( $0.05 \mu\text{g ml}^{-1}$ ). In a third experiment (H) a final concentration of 0.075 M hydroxyurea was added to the culture medium. Both substrate limitation conditions reduce the rate of DNA synthesis about 20-fold. After about a 50% increase in cell mass during substrate limitation, DNA was prepared from the cells. Replicating R plasmid DNA molecules were fractionated by caesium chloride preparative density gradient centrifugation<sup>11</sup>. Fractionated R plasmid DNA was spread for electron microscopy at pH 10.7. Replicating, circular NR1 DNA molecules which had on the order of 20 small denaturation sites, were photographed and analysed<sup>12</sup>. The denaturation sites are represented by the smaller vertical bars of varying width, the width of the bars being proportional to the size of the denaturation site. From the distribution of denaturation sites on the replicating molecules, the molecules were aligned relative to the composite NR1 DNA denaturation map<sup>12</sup>. All the replicating molecules shown here are circular structures which have been superimposed on a linear composite NR1 DNA denaturation map for convenience of presentation. The extent of replication and the replication branch positions of individual molecules are designated by the arrows between the two larger vertical bars. Since the replicating molecules are circular, the arrows representing the replication branch positions have been extended through the 0.0/1.00 junction of the denaturation map to avoid interruption. In these cases, the extended part of the arrows is repeated as a dashed arrow at the corresponding region at the other end of the denaturation map. Molecules whose replication branches are consistent with the r-determinants origin of replication are shown in the group of molecules included in *a* and molecules consistent with the RTF origin are shown in the group of molecules included in *b*. The molecules in each of the classes *a* and *b* are divided into three subclasses depending on whether replication is unidirectional to the right (*a*<sub>1</sub> and *b*<sub>2</sub>) or unidirectional to the left (*a*<sub>2</sub> and *b*<sub>1</sub>); replicating molecules showing bidirectional replication are included in *a*<sub>3</sub> and *b*<sub>3</sub>.

All 10 replicating molecules in the first thymine limitation experiment (T1 molecules) were found to initiate replication at the RTF origin. In the case of the T2 replicating molecules and the H replicating molecules, however, about three-quarters of the molecules used the r-determinants origin and only a quarter the RTF origin. Since only a relatively small number of molecules were examined in each experiment, the data do not give a statistically accurate value for the frequency of use of

in eukaryotic chromosomes using electron microscopy<sup>20</sup> and autoradiography<sup>21</sup>, indicating that there are multiple origins of replication. Poly-r-determinant R plasmids<sup>5-7,9,10</sup> must also contain multiple origins of replication, the number depending on the number of copies of r-determinants. Analysis of replicating poly-r-determinant R plasmid DNA by denaturation mapping should make it possible to determine whether there is any specificity involved in the selection of an origin for the initiation of

Fig. 3 Weight-average histogram of the distribution of denaturation sites in aligned replicating molecules of composite R plasmid NR1 DNA. *a*, Histogram constructed from the distribution of denaturation sites in the replicating NR1 DNA molecules shown in Fig. 2. The histogram includes all the denaturations present in the replicating molecules, even those present in the sister replication branches of the same molecule. *b*, Denaturation map of non-replicating composite R plasmid NR1 DNA<sup>12</sup>.

either origin for the initiation of replication. Other experiments in which the total replicating plasmid DNA has been analysed (rather than individual replicating molecules in an electron microscope) also indicate that there is preferential use of the r-determinants origin. These experiments involve DNA-DNA hybridisation and buoyant density analysis of replicating R plasmid DNA and Agarose gel analysis of the fragments of replicating R plasmid DNA produced by treatment with restriction endonuclease *EcoRI* (D.P. and R.R., in preparation).

Our experiments have shown that there are at least two functional origins of replication in composite R plasmid NR1 DNA. The use of both origins is of course not mandatory since one origin might be dominant to the other in the initiation of replication. For example, the bacterial chromosome origin is dominant to the F factor origin in an Hfr strain<sup>13</sup> or to a prophage origin in a lysogenic strain<sup>14</sup> of bacteria. It is presently not known what determines the selection of either of the two origins for the initiation of composite R plasmid replication. It is possible that the substrate limitation technique itself could affect the selection. Since R plasmid NR1 replication is arrested when protein synthesis is inhibited<sup>6,15</sup>, it will be of interest to determine whether there are specific R plasmid initiator proteins for each of the two origins or whether the same initiator proteins can function at either of the two origins.

Like phage  $\lambda$  DNA<sup>16</sup>, R plasmid DNA is replicated either bidirectionally or unidirectionally in either sense. Colicin E1 plasmid DNA, on the other hand, replicates unidirectionally from a unique origin<sup>17-19</sup>. Thus, in the two examples of plasmid replication which have been examined, different modes of replication have been observed.

Several internal replicating regions have been observed

replication, whether the additional r-determinants origins on poly-r-determinant R plasmids will influence the frequency of selection of the r-determinants origin relative to the RTF origin, and whether multiple initiations can occur on the same replicating R plasmid DNA molecule.

# Replication control in a composite plasmid constructed by *in vitro* linkage of two distinct replicons

Felipe Cabello, Kenneth Timmis & Stanley N. Cohen

Department of Medicine, Stanford University School of Medicine, Stanford, California 94305

*Although it carries two competent replication systems, a composite plasmid formed in vitro by linkage of the complete ColE1 and pSC101 plasmid replicons at their unique EcoRI endonuclease cleavage sites normally uses only the replication origin and functions of the ColE1 component. Restriction of ColE1 replication functions by DNA polymerase I deprivation results, however, in exclusive use of the pSC101 replication origin. When using the ColE1 replication system the composite plasmid is nevertheless incompatible with both the parent replicons. This suggests that a trans-dominant gene product is involved in plasmid incompatibility and supports negative control rather than positive control models for regulation of the initiation of DNA replication.*

INITIATION of DNA replication usually occurs at a unique site on the DNA molecule—the replication origin—by covalent attachment of deoxyribonucleotides to a short chain of primer RNA<sup>1</sup>, designated origin RNA<sup>2</sup>. A few replicons, however, have been reported to contain and sometimes utilise more than one replication origin (*Drosophila melanogaster* chromosomal DNA<sup>3</sup>; mitochondrial DNA oligomers<sup>4</sup>; *Escherichia coli* plasmids NR1 (ref. 5) and RSF1040 (ref. 6)), although little is known about the control of origin usage in such systems.

To gain information on how multiple regions of replication activity (replication origin plus associated essential replication functions) present on a single DNA molecule function and interact, we have constructed a model replicon (the pSC134 plasmid) by *in vitro* linkage of the colicin plasmid ColE1 and the tetracycline resistance plasmid pSC101 from *E. coli* at their unique *EcoRI* restriction endonuclease cleavage sites<sup>7</sup>. Since the ColE1 plasmid cannot replicate in bacteria deficient in DNA polymerase I<sup>8</sup> and the pSC101 plasmid cannot replicate in bacteria not actively engaged in protein synthesis<sup>9</sup>, the two components of the pSC134 composite plasmid have functionally distinguishable replication properties. It was possible therefore to show that each component replication system of the hybrid could accomplish replication of the entire molecule. The present study is an investigation of the functioning of the two replication origins of the pSC134 composite plasmid and its incompatibility properties.

## Location of replication origin of pSC101

Treatment of the composite plasmid pSC134 with *EcoRI* restriction endonuclease generates unit length linear forms of the parent plasmids, ColE1 and pSC101, which can be distinguished easily in the electron microscope by their different sizes (4.2 and 5.8 megadaltons respectively<sup>9,10</sup>). Although it is largely possible to distinguish replication origin usage by the two components of pSC134 by determining the size of the *EcoRI* endonuclease-generated fragments which contain replication 'eyes', the unambiguous identification of such fragments

depends on the determination of origin location, since preparations of *EcoRI*-cleaved DNA may contain some fragments produced by random breakage. The replication origin of plasmid ColE1 has previously been found to lie 18% of the molecule length from the unique *EcoRI* cleavage site of this plasmid. Replication proceeds unidirectionally from this origin<sup>11-13</sup>. The location of the replication origin of the pSC101 plasmid has not been reported, however, and to identify unequivocally pSC101 origin usage by the pSC134 hybrid, we first determined the location of the replication origin of the pSC101 plasmid in relation to the unique *EcoRI* cleavage site of the plasmid.

Replicating molecules of pSC101 were prepared by standard methods<sup>6,11</sup> from radioactive thymidine pulse-labelled cells of *E. coli* K12 (pSC101) (Fig. 1a) and examined by electron microscopy after X-ray treatment to relax supertwisted DNA or after *EcoRI* endonuclease digestion (Fig. 1b). Circular replicating molecules were observed to contain a single replication eye, which suggested that the pSC101 plasmid probably contains a single replication origin. This interpretation was confirmed by an examination of *EcoRI* endonuclease-cleaved replicating molecules. Linear molecules which contained a replication eye were photographed (Fig. 1b) and the unreplicated arms and newly replicated segments were measured (Fig. 1c). It may be seen that for molecules less than 50% replicated, one unreplicated arm remains constant in size, whereas the other decreases progressively in length. The pSC101 plasmid therefore replicates unidirectionally. Extrapolation of the plots of relative lengths of unreplicated arms as a function of percentage replication to 0% replication indicates that the pSC101 origin is located about 50% of the unit length from the *EcoRI* cleavage site.

## Replication origin usage by pSC134

To determine whether one or both of the potential replication origins of the pSC134 composite plasmid are active during normal replication of the pSC134 plasmid (that is, in conditions in which neither set of replication functions is deliberately inhibited) and to measure the relative activity of each of the possible origins, replicating molecules of pSC134 were prepared and examined as described for the pSC101 plasmid. Of 97 circular replicating molecules observed (see Fig. 2a for example), only one seemed to have two replication eyes (Fig. 2a, 6). Thus, utilisation of both origins during replication of a single molecule is very rare. Indeed such an event may be an aberrant replication process which would fail to produce functional progeny molecules.

Examination of *EcoRI* cleaved replicating forms of pSC134 revealed that the ColE1 replication origin was used exclusively during normal replication of the composite plasmid: all of 36 *EcoRI*-generated fragments of pSC134 which contained a replication eye had molecular lengths similar to that of ColE1 (Table 1). Furthermore, a plot of the relative lengths of the unreplicated arm against the extent of replication of these fragments (Fig. 2a) indicated that replication of the composite plasmid begins 18% from the nearest *EcoRI*-generated terminus of the ColE1 segment and proceeds unidirectionally away from

that terminus, as reported previously for ColE1 (refs 11–13). Thus, the location of the replication origin and the direction of replication from this origin in the pSC134 composite plasmid are identical to those of the ColE1 parent.

**Fig. 1** Location of replication origin of plasmid pSC101. *a*, Isolation of replicative intermediates. Cells of *E. coli* K12 CR34 (ref. 34) *nal<sup>r</sup>* (pSC101) were grown with aeration at 37 °C in 250 ml M9 minimal medium containing 0.5% casamino acids, 10  $\mu\text{g ml}^{-1}$  thiamine, 3  $\mu\text{g ml}^{-1}$  thymidine and 0.4  $\mu\text{Ci ml}^{-1}$   $^{14}\text{C}$ -thymidine to an  $A_{590}$  of 0.4, centrifuged at 8,000*g* for 5 min at 20 °C, and resuspended in fresh medium without thymidine. The culture was starved for thymidine by incubation at 37 °C for 30 min. It was then cooled to 20 °C and pulse-labelled by addition of thymidine to 0.3  $\mu\text{g ml}^{-1}$  and  $^3\text{H}$ -thymidine to 10  $\mu\text{Ci ml}^{-1}$ . The pulse was terminated after 30 s by pouring the culture into a large flask which was cooled in a dry ice-isopropanol bath and which contained ice and KCN (final concentration 20 mM). Cells were washed twice with ice-cold TE-KCN (Tris-HCl 10 mM pH 8.0-EDTA 1 mM-KCN 20 mM) resuspended in 2.5 ml 25% sucrose in Tris-HCl (0.25 M pH 8.0)-KCN (20 mM) and lysed by the successive addition of 0.5 ml lysozyme (10 mg  $\text{ml}^{-1}$ ), 1 ml EDTA (0.25 M, pH 8.0) and 4 ml of 10% Triton X-100 in Tris-HCl (0.05 M pH 8.0)-EDTA (0.063 M). The lysate was then centrifuged at 50,000*g* for 15 min at 0 °C to remove the bulk of chromosomal DNA and the supernatant fluid was added to 8 g CsCl plus 1 ml of ethidium bromide (10 mg  $\text{ml}^{-1}$ ) and was subjected to equilibrium centrifugation (at 36,000 r.p.m. for 60 h at 20 °C in the Beckman 50Ti rotor). Fractions were collected from the bottom of the centrifuge tube and the cold trichloroacetic acid precipitable radioactivity present in a 25- $\mu\text{l}$  aliquot of each fraction was determined. The lower panel shows the distribution of the  $^{14}\text{C}$  radioactivity (uniformly-labelled DNA) and the  $^3\text{H}$  radioactivity (pulse-labelled DNA). The upper panel shows the ratio of  $^3\text{H}$  to  $^{14}\text{C}$ . As has been observed for several circular DNA molecules<sup>1</sup>, the pulse-labelled material is found predominantly between the closed circular and open circular positions in the CsCl-ethidium bromide gradient. This indicates that replicative intermediates of the pSC101 plasmid have a closed-circular duplex component. It should be noted that some pulse label is found at a more dense region of the gradient than that where the closed circular plasmid DNA bands. The pulse-labelled DNA which sediments at this position represents a novel form of replicative intermediate which has also been observed recently by others (J. H. Crosa, personal communication; Y. Kupersztoch, personal communication) and which will be described in detail elsewhere (K.T., F.C., and S.N.C., in preparation; J. H. Crosa, L. K. Luttrupp and S. Falkow, in preparation). *b*, Electron microscopy of *EcoRI*-cleaved replicative intermediates. The material from the CsCl-ethidium bromide gradient represented by the hatched area in *a* was extracted with isopropanol

Coexisting independent pSC101 and ColE1 plasmids cannot provide in *trans* replication functions for each other<sup>7</sup>, suggesting that our previously observed replication of the composite plasmid in conditions of DNA polymerase I deprivation

to remove the ethidium bromide, dialysed 3 h at 4 °C against 1 l of TE buffer (two changes), treated with *EcoRI* (ref. 35) for 15 min at 30 °C and the DNA mounted for electron microscopy using the basic protein film technique<sup>36</sup> as described by Davis *et al.*<sup>37</sup> (ColD-CA23 (ref. 7), was used as an internal contour length reference). Grids were rotary shadowed with platinum-palladium and examined in a Philips EM201 electron microscope. *EcoRI*-cleaved molecules containing replication eyes or forks were photographed and measured and the fractional lengths of replicated and unreplicated segments were calculated and plotted as shown in *c*. Replicating molecules displaying whiskers<sup>38</sup>, which were assumed to have arisen by the process of branch migration during the isolation period, were ignored for the purposes of this experiment.

occurred by means of the pSC101 origin. To test this directly, we prepared replicating molecules of pSC134 from bacteria deficient in DNA polymerase I (*E. coli* W3110 *polA1*, ref. 14) and determined replication origin usage as described above. It was found that in such bacteria, the pSC134 hybrid utilises its pSC101 replication origin exclusively (Table 1) providing direct evidence that the pSC101 replication origin can function in the hybrid plasmid.

### Plasmid copy number

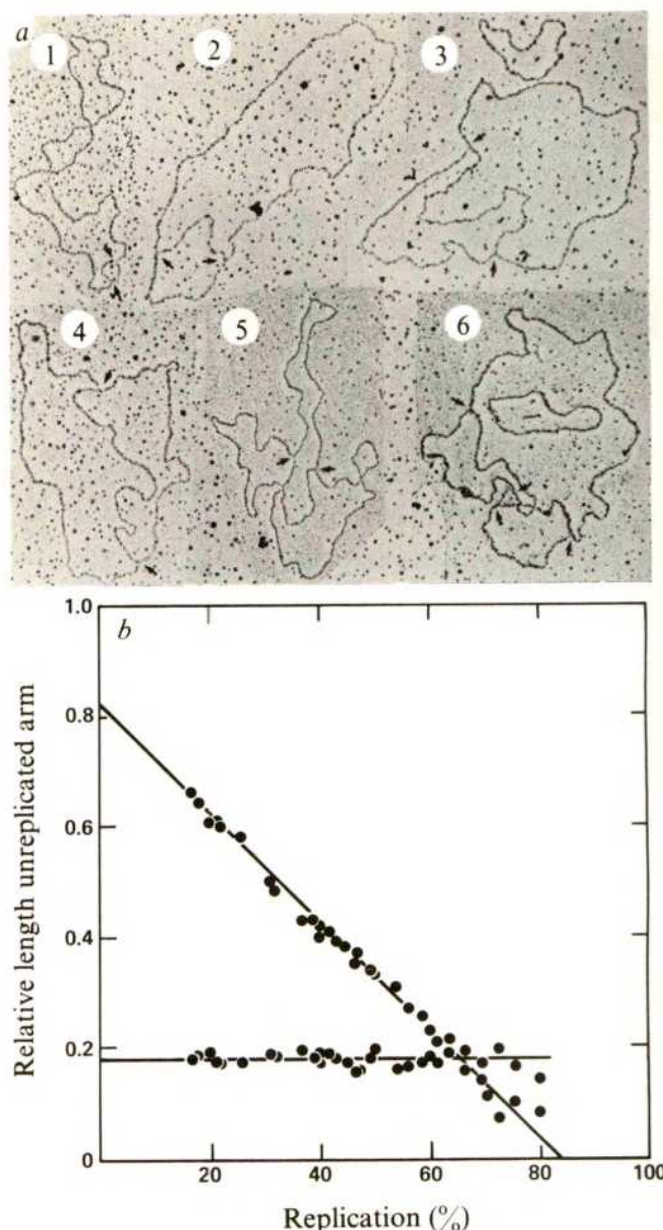

Although we have shown previously that both ColE1 and pSC101 replication functions are individually competent to replicate the entire pSC134 molecule<sup>7</sup>, it was not known whether one or both sets of functions are involved in the normal replication of the hybrid plasmid. Nordström, and Kool and Nijkamp have shown that for the R1 (ref. 15) and CloDF13 (ref. 16) plasmids, at least one product that controls the number of copies of a plasmid in a cell is encoded by the plasmid. Copy number seems to be a property of plasmid replication and may be regulated by a repressor of replication; copy number mutants frequently show altered incompatibility properties<sup>17</sup>. Moreover, the replication, copy number and incompatibility functions were shown to be clustered on a single *EcoRI*-generated DNA fragment in the case of the *F'-lac* and R6-5 plasmids<sup>18</sup>.

Since the replication functions of the pSC101 and ColE1 plasmids are apparently active only on the homologous replication origin (above, and ref. 7), exclusive use of the ColE1 origin during normal replication of the composite plasmid implies that ColE1 replication functions are being used. ColE1 and pSC101 have distinct copy numbers in logarithmically-growing cells (see below); thus determination of copy number of the composite plasmid should elucidate which of the parent plasmid copy number regulating factors is active in its replication.

Table 1 shows that under non-restrictive conditions of bacterial cell growth, the ColE1 and pSC101 plasmids have average copy numbers of 18 and 6 per genome equivalent, respectively. Coexistence of independently-replicating ColE1 and pSC101 plasmids in the same cell does not appreciably affect their relative copy number. In our experimental conditions, the pSC134 hybrid plasmid has a copy number of 16 and so exhibits the copy number characteristic of its ColE1 component. If ColE1 replication functions are inhibited by DNA polymerase I-deprivation, however, the composite replicon is maintained at a copy number typical of the pSC101 plasmid (Table 1). Thus, plasmid copy number correlates with and seems to be an indicator of the system that is being used to replicate the hybrid plasmid.

### Tetracycline resistance level

The plasmid copy numbers given above were determined by direct quantitation of plasmid DNA by density gradient centrifugation; they are supported by data showing the level of tetracycline (Tc) resistance expressed by the pSC134 hybrid and its parent pSC101 plasmid. The minimum inhibitory concentration (MIC) of Tc for cells carrying the pSC101 plasmid is about  $30 \mu\text{g ml}^{-1}$  whereas the MIC for cells carrying the pSC134 plasmid is about  $80 \mu\text{g ml}^{-1}$  (Table 1). The increased resistance specified by the pSC134 plasmid is not simply due to the presence of ColE1 in the cells since bacteria carrying pSC101 and ColE1 as independent replicons are resistant to only  $30 \mu\text{g ml}^{-1}$  of antibiotic. Furthermore, the observed increased resistance is not the result of changes in transcription/translation of the Tc-resistance gene in the pSC134 plasmid as a consequence of hybrid formation, since the hybrid confers resistance to only  $30 \mu\text{g ml}^{-1}$  of Tc in cells deficient in DNA polymerase I, which maintain pSC134 at the same copy number as pSC101. We conclude that the increased resistance to Tc of cells carrying the pSC134 plasmid must result from increase in the number of Tc gene

**Fig. 2** Plasmid pSC134 normally utilises its ColE1 replication origin. Replicative intermediates of plasmid pSC134 were isolated as described in Fig. 1 and either nicked by X irradiation to relax supercoiled molecules (a) or treated with *EcoRI*. The molecules were then examined by electron microscopy as described in Fig. 1. The small molecules present in 3 and 6 are ColD reference molecules. *EcoRI*-generated fragments containing replication eyes or forks were photographed and measured. All had contour lengths corresponding to that of ColE1. Fractional lengths of replicated and unreplicated segments of these molecules are displayed in b. It can be seen that the replication origin on these fragments is located 18% from one *EcoRI*-generated terminus and that replication proceeds away from this proximal terminus, as has been previously shown for ColE1<sup>11-13</sup>.

copies (plasmid copy number) from 6 to 16 per genome equivalent and reflects a gene dosage effect.

Unlike most other kinds of plasmid-borne antibiotic resistance, in which plasmid-specified antibiotic-modifying enzymes are produced, Tc resistance seems to result from plasmid-induced changes in bacterial cell membrane permeability<sup>19</sup>. Thus there has been discussion as to whether Tc resistance could exhibit gene dosage effects<sup>20</sup>, as has been observed for plasmid-specified proteins<sup>15, 21, 22</sup>. Our data and the recent results of

**Table 1** Replication origins and functions utilised by plasmid pSC134

<i>E. coli</i> strain	Replication origin usage ColE1	pSC101	Plasmid copy number	Level of Tc resistance
CR34 <i>polA</i> <sup>+</sup> (pSC134)	36	0	16	80
W3110 <i>polA</i> <sup>-</sup> (pSC134)	0	14	6	25
CR34 <i>polA</i> <sup>+</sup> (pSC101)	—	—	5	25
C600 <i>polA</i> <sup>+</sup> (ColE1, pSC101)	—	—	18, 5	30

Origin usage by pSC134 in cells either wild type (*E. coli* CR34, ref. 34) or deficient (JG112 = W3110 *polA*<sup>-</sup>, ref. 14) for DNA polymerase I was determined by electron microscopy of *Eco*RI-cleaved replicative intermediates prepared as in Fig. 1 (only a few replicating pSC134 molecules were observed in DNA prepared from strain JG112). The plasmid copy number is a minimum value of the number of plasmid copies per genome equivalent. Values obtained by centrifugation of Sarkosyl crude cell lysates to equilibrium in CsCl-ethidium bromide gradients<sup>7</sup> and by sedimentation of cleared lysates through neutral sucrose gradients<sup>7</sup> were in close agreement. The level of tetracycline (Tc) resistance exhibited by the different bacteria is expressed as a minimum inhibitory concentration (MIC) in  $\mu\text{g ml}^{-1}$ , as determined by spreading about 100 cells on nutrient agar plates containing the antibiotic at different concentrations. The copy number and Tc-resistance level characteristics of the pSC101 plasmid were comparable in *polA*<sup>-</sup> and *polA*<sup>+</sup> bacteria.

Clewell *et al.*<sup>23</sup> indicate that plasmid specified Tc resistance is affected by changes in gene dosage.

### Incompatibility of pSC134 with parent replicons

Elucidation of the relationship between use of a particular replication system by a plasmid and the plasmid's incompatibility properties was an important objective of the present study. Earlier studies of incompatibility between related plasmids have been restricted to replicons which have acquired distinguishing phenotypic traits by genetic recombination *in vivo* (ref. 24 for example). Although incompatibility of recombinant plasmids with the parent replicons or related plasmids has been demonstrated<sup>42,43</sup>, the propinquity of incompatibility properties to plasmid replication could not be determined. DNA cloning methods<sup>25</sup>, however, now enable the construction of marked plasmids with identical replication systems. A series of *Eco*RI restriction endonuclease-generated DNA fragments that code for different antibiotic resistance genes (Ap, Km, SuSm) have recently been isolated from antibiotic resistance plasmids, and have been individually inserted *in vitro* into the separate ColE1 and pSC101 replicons (refs 18, 22, 25, 26 and K.T., F.C., and S.N.C., in preparation). Using such constructed molecules, the clonal inheritance of plasmids known to have identical replication functions can easily be followed during incompatibility studies by means of their different antibiotic resistances.

Incompatibility studies were carried out for the pSC134 composite replicon using ColE1-Ap, ColE1-SmSu, pSC101-Km, and pSC101-Ap derivative plasmids. Our results indicate that pSC134 is incompatible with both parent plasmids, despite its normal use of the ColE1 replication functions and origin only. The rate of segregation of pSC134 and ColE1-SmSu (Fig. 3c) is comparable with the segregation rate observed with the ColE1-Ap and ColE1-SmSu plasmids (Fig. 3d). In contrast, the segregation rate observed between pSC134 and pSC101-Km (Fig. 3a) is much greater than between pSC101-Km and pSC101-Ap (Fig. 3b).

### Models for the control of initiation of DNA replication

The studies reported here have used a specifically designed and constructed composite plasmid replicon for investigation of control mechanisms regulating plasmid replication, copy number, and incompatibility. Our results indicate that although the hybrid plasmid replicon pSC134 can use either of its two component replication systems, in normal conditions only its ColE1 replication functions and origin are used. The copy number of the composite plasmid is maintained at the ColE1 level. When the ColE1 replication functions are inhibited by DNA polymerase I deprivation, control of replication occurs by means of the origin and functions of the pSC101 component, and the copy number falls to a level typical of that plasmid. Moreover, although only the ColE1 replication system is

normally used by the composite plasmid, in such circumstances it is nevertheless incompatible with both of its parent replicons. These various features of replication of the pSC134 composite plasmid must be taken into account by any suitable model for control of the initiation of DNA replication.

The replicon model of Jacob, Brenner and Cuzin<sup>27</sup>, a positive control model, postulates that replication and maintenance of replicons takes place on cell membrane attachment sites. Replication occurs when the sites are duplicated and progeny molecules are subsequently distributed among daughter bacteria at cell division. According to this model, compatible plasmids have different membrane attachment sites, whereas incompatible plasmids compete for the same sites; incompatible plasmids initially present in the same cell thus segregate at cell division. Since both ColE1 and pSC101 replication origins and functions have been shown to be available for replication of the pSC134 composite plasmid, a prediction of the model of Jacob *et al.* is that each of the component systems should be used to replicate some plasmid molecules. Therefore, this model would predict that pSC134 should have a copy number similar to the additive plasmid copy number in cells carrying independently-replicating ColE1 and pSC101 plasmids, since each component replicon should be capable of producing its normal complement of copies whether or not it is physically linked to a second replicon. Finally, the model of Jacob *et al.* predicts that the pSC134 plasmid should be compatible with its pSC101 parent, since the hybrid replicon uses only its ColE1 replication origin and functions for normal replication, and thus should not compete for any pSC101-specific bacterial cell membrane replication sites. These predictions are not fulfilled by our experimental findings.

An alternative model involving negative control of initiation of DNA replication proposed by Pritchard, Barth, and Collins<sup>28</sup> postulates that a replication repressor substance is involved in the control of initiation of DNA synthesis. Replication is initiated when the repressor is diluted out to a critical concentration during the course of cell growth (that is, when a critical cell mass per replicon, the initiation mass, is achieved). If incompatible plasmids specify identical or similar initiation repressors, as required by this model, the total number of copies of the two plasmids could not exceed the usual copy number of one of them alone. Segregation of the two incompatible replicons would then occur at cell division. This model predicts that regardless of the replication functions used by the pSC134 hybrid plasmid, it should direct the synthesis of both types of initiation repressor, and thus should be incompatible with both parent plasmids (or derivatives thereof).

Implicit in the Pritchard *et al.* model is the expectation that a low copy number (high initiation mass) plasmid will be inhibited at low effective concentrations of its specific repressor, whereas greater effective concentrations of the repressor of a high copy number (low initiation mass) plasmid are required to inhibit its replication. Consequently, if two replicons such as ColE1 and pSC101 (which have different copy number) are fused, replication of the hybrid will be controlled by the ColE1 component<sup>29</sup>. Replication of this component will be prevented

**Fig. 3** Incompatibility properties of pSC134. The *in vitro* construction of the pSC101 derivatives pSC101-Ap (pSC122) and pSC101-Km (pSC105) which code for resistance to ampicillin and kanamycin, respectively, has been described<sup>18,25</sup>. ColE1-Ap (pSC142) was constructed by insertion of Ap-DNA isolated from pSC122 into the *EcoRI* site of ColE1. ColE1-SmSu (pSC143) contains an *EcoRI* fragment coding for resistance to streptomycin (Sm) and sulphonamide (Su) from R6-5 (K. T., F. C., and S. N. C., in preparation). Plasmids pSC134, pSC142, and pSC105 were introduced into *E. coli* K12 HfrC (strain W2252 kindly provided by A. Ganesan) by transformation<sup>26</sup>. After transformants had been purified by single colony isolation, their donor ability was determined using MS2 bacteriophage. These plasmids were then transferred by conjugation to *E. coli* K12 CR34 NaI<sup>r</sup> bacteria containing pSC105, pSC122, or pSC143. Transconjugants were selected on media containing nalidixic acid (50  $\mu\text{g ml}^{-1}$ ) and the combinations of antibiotics required to select both plasmids. Antibiotics were used at the following concentrations: Ap and Km 50  $\mu\text{g ml}^{-1}$ , Sm 25  $\mu\text{g ml}^{-1}$ , and Tc 10  $\mu\text{g ml}^{-1}$ . Transconjugant colonies which appeared on the double selection plates were used directly for segregation studies. Segregation of the plasmids was followed by picking colonies to flasks containing L-Broth plus nalidixic acid and allowing the bacteria to grow for about 25 generations in the absence of other antibiotics. At intervals samples were plated on nutrient agar. Colonies which appeared on these plates subsequently were toothpicked to nutrient agar plates containing appropriate antibiotics to determine which plasmids were present in the clone. The data plotted indicate the fraction of cells containing both plasmids. The segregation pattern thus obtained for the various plasmid combinations is shown in panels a-e. Because the pSC134 plasmid and pSC101 derivatives code for Tc resistance, the segregation of pSC134 in cells carrying pSC101 derivatives was monitored on colicin E1-containing media by means of the colicin E1-immunity (E1-imm) coded by pSC134 (colicin E1 was prepared and assayed as described in refs 40 and 41). In the panels, the first component of each plasmid pair is the incoming plasmid and the second component is the resident. With all plasmid combinations except the one represented in panel a, the incoming plasmid could be either member of the pair. The pSC105 plasmid, however, could not be introduced into bacterial cells already carrying pSC134. In a and d it can be seen that some segregation had already occurred in the clones selected before the beginning of the experiment. This is probably due to destruction of antibiotic in and around the clone by enzymes specified by one plasmid.

only when the hybrid plasmid reaches the high copy number required to produce effective inhibitory concentrations of the ColE1 replication repressor substance, whereas pSC101 replication is prevented by the pSC101 repressor substance at low copy number. Because the pSC101 repressor is always in excess when copy number of the composite plasmid is high, replication activity of the pSC101 component of the composite plasmid should be prevented so long as the ColE1 replication system is functioning. A second pSC101 replicon that is introduced into a cell carrying pSC134 (Fig. 3a) similarly should be prevented from replicating. Inhibition of the ColE1 replication system of the composite replicon results in a drop in plasmid copy number to a level where the pSC101 replication system is now able to act. When copy number of the pSC101 replicon is not forced up by its attachment to the ColE1 replicon (that is, when the two plasmids coexist autonomously in the same cell) pSC101 is able to maintain its own control of copy number and utilise its own replication origin and functions despite the presence of ColE1.

The replication properties of the pSC134 composite plasmid seem not to be explicable in terms of the positive control replicon model. The simplest interpretation of our results implicates a replication origin-specific, freely diffusible plasmid gene product that functions by negative control of DNA synthesis and, to that extent, our findings support the general model for DNA replication control proposed by Pritchard *et al.* The present studies do not, however, concern the other major aspect of this model, namely the suggestion that the timing of initiation of DNA replication is controlled by the process of dilution of the initiation repressor during cell growth. An adequate explanation for phenomena such as relaxed replication (for definition see ref. 7) of certain plasmids in non-dividing stationary phase bacterial cultures may require a more elaborate concept than that of inhibitor dilution.

Recent evidence indicates that discrete segments of DNA can be translocated from plasmid to plasmid by non-reciprocal recombinational events<sup>30-33</sup>. Such events could lead to the formation of naturally-occurring replicons with multiple replication origins and functions. Experimentally, such plasmids may appear to contain a single replication origin if their component segments are derived from replication systems that specify different copy number, as is pSC134. Conversely, we can speculate that replicons which are observed to use more than one origin during normal replication are derived from plasmids with similar copy number. Presumably this may occur by the recombination of genetically different replication systems which coincidentally specify a similar copy number, by recombination of closely related replication systems derived from different plasmids, or by duplication of the origin of a single plasmid.

Since the pSC134 hybrid plasmid can utilise either one of its replication systems to propagate itself in conditions that are restrictive for the other region of replication activity, it is a bifunctional replicon. Other such replicons can be constructed to contain dual replication regions derived from diverse biological sources; they are potentially highly useful for the development of DNA cloning systems for hosts other than *E. coli*. Moreover, the ability of the pSC134 plasmid to propagate in *E. coli* by using either of its replication systems now provides a valuable tool for the isolation of plasmid mutants that are defective in one of the pSC134 component replicons.

We thank J. Crosa, W. Messer, R. H. Pritchard and M. Lovett for helpful advice and stimulating discussions. This research was supported by grants from the National Institute of Allergy and Infectious Diseases, the National Science Foundation and the American Cancer Society. # letters to nature

## Can 'invisible' bodies be observed in the Solar System?

MANY theories of the origin of comets predict that there are  $\sim 10^{11}$  comets in the Solar System; most of them, unfortunately, at such a distance that they can never be observed. Some theories go even further and predict that, in addition to these comets in the Oort cloud, the remains of a primaeval comet belt may still exist at a distance of  $\sim 50$  AU. This idea has been investigated by Hamid *et al.*<sup>1</sup>, who show (from an analysis of observed perturbations on Halley's comet) that the total mass of the comet belt must be  $\lesssim 1$  Earth mass. Even this relatively small mass would be enough for  $\sim 10^{10}$  comets—a significant fraction of the total of the whole Oort cloud. It has been noted that comets contain a relatively large fraction of 'heavy' elements, and it has been suggested<sup>2</sup> that the total galactic population of comets may be large enough to affect significantly the chemical evolution of the Galaxy by acting as a 'sink' for the heavy elements.

The absence of observations of strongly hyperbolic orbits places a limit on the total mass of interstellar comets, but there remains the possibility that a great many comets may be permanently bound to their 'parent' star, and will thus always remain unobserved. Whipple<sup>3</sup> has considered this possibility and concludes that a mass  $>0.01M_{\odot}$  could be distributed as comets in the inner region of the Oort cloud (from 50 to  $\sim 20,000$  AU) and continue to remain undetected by present methods. It is clear that techniques based on the gravitational effect of hypothetical comets on observed ones are not yet sufficiently well developed to limit speculation, and it is my purpose to suggest a way in which this might be done.

Consider a 'boulder' in the Solar System of radius  $R$  and geocentric distance  $d$ . Its angular diameter is  $\theta = 2R/d$ ; similarly, the angular diameter of a star is  $\theta_* = 2R_*/d_*$ . The boulder can occult the star if  $\theta > \theta_*$ , that is if

$$Rd_*/R_*d > 1 \quad (1)$$

If the geocentric transverse velocity of the boulder is  $v_t$ , it will seem to move its own diameter in a time,  $\tau$ , where  $\tau = 2R/v_t$ .

The boulder therefore 'sweeps' a narrow track on the celestial sphere at a rate

$$\dot{A} = \theta^2/\tau = 2Rv_t/d^2 \quad (2)$$

Should there be  $n$  such boulders per steradian the whole sky can be considered to have been swept after a time  $T$ , where  $nAT \simeq 1$ , giving

$$T \simeq d^2/2nRv_t \quad (3)$$

If one is able to monitor  $n_*$  stars continuously, each satisfying the criterion (1), on the average one should observe an occultation once every

$$T' \simeq d^2/2nn_*Rv_t \quad (4)$$

As an example, we shall consider the possibility of detecting the hypothetical comet belt at  $\sim 50$  AU. To obtain a rough estimate of  $T'$  we shall suppose that the belt consists of  $N$  identical comet nuclei, each of radius  $R$  and density  $\rho$ . If the upper limit to the mass of the belt is  $M_u$  we have

$$N \lesssim M_u/(4/3)\pi\rho R^3 \quad (5)$$

One would expect the comets to show some concentration towards the ecliptic, and as a rough approximation we shall assume that the  $N$  comets are distributed over 2 sr of the celestial sphere. This means that  $n \simeq N/2$ , or

$$n \lesssim \frac{1}{2} M_u/(4/3)\pi\rho R^3 \quad (6)$$

then, from equation (4)

$$T' \gtrsim 4\rho R^2 d^2/n_* M_u v_t \quad (7)$$

For  $v_t = 10 \text{ km s}^{-1}$ ,  $R = 3 \text{ km}$ ,  $d = 50 \text{ AU}$ ,  $M_u = 5 \times 10^{24} \text{ kg}$ , and  $\rho = 10^3 \text{ kg m}^{-3}$ , we find

$$T' \gtrsim 4 \times 10^7/n_* \text{ s} \quad (8)$$

It is of interest to estimate the number of stars,  $n_*$ , that could be successfully monitored using existing technology. Perhaps the most suitable detector for the purpose is a SIT Vidicon

system, which scans a large area with high sensitivity and good time resolution. Noise in the system arises primarily from photon statistics, and for the following estimate of  $n_*$  it will be assumed that this is the only source of noise. Assuming that a 0 mag star produces  $\sim 1,000$  photons  $\text{\AA}^{-1} \text{cm}^{-2} \text{s}^{-1}$ , and that the photocathode has a bandwidth of  $3,000 \text{\AA}$  with a mean quantum efficiency of 15% (for example S-20), it can be shown that the contribution to the signal in a 1 m telescope from a 16 mag star is  $\sim 140$  photon events per 0.1 s. Taking the sky background to be equivalent to one 21 mag\* per square second of arc, and the resolution of the vidicon to be  $10''$ , we have  $S_* \simeq S_B$ . The total signal therefore consists of  $\sim 280$  photon events per 0.1-s interval, of which  $\sim 140$  on average come from the star. A fairly safe criterion for the occurrence of an occultation would be to count an 'event' each time the signal in any 0.1 s interval falls below that corresponding to 160 photon events. (Assuming that the photon events obey a Poisson distribution, the probability of such a fluctuation would be  $< 10^{-13}$ ; whereas equation (8) shows that the probability of an occultation is  $\sim 2.5 \times 10^{-9}$  per 0.1 s.) The statistics could be greatly improved for the case of occultations lasting longer than 0.2 s. A vidicon tube consisting of a  $300 \times 300$  array of resolution elements, each with the stated resolution, will be able to monitor  $\sim 0.7$  square degrees of sky which, considering stars brighter than 16 mag will contain  $\sim 1,000$  stars. With  $n_* = 1,000$ , the waiting time between occultations reduces to  $\sim 11$  h. One consequence of the use of such a technique would be that  $M_u$  would continually decrease if no occultation was seen. It should be emphasised that the figure of 11 h observing time per 'event' could almost certainly be greatly improved if an instrument was purpose built for the detection of occultations.

The above is meant only to illustrate the possibilities for such an observational technique. A complete theory would have to be statistical in nature, and the interpretation of a particular event would depend on the distributions of  $R$ ,  $d$ , and  $v$ , that one might expect to encounter. One would like, for example, to be able to distinguish between a boulder at 1 AU and a comet nucleus at 100 AU. If the detector system could be made sufficiently sensitive to be able to record 'partial' occultations, the detection of a variety of interplanetary debris may be possible and, in particular, the detection of comets at distances  $\gg 50$  AU would be possible. The technological problems involved in the design and construction of such a detector promise to be large, but should not be insurmountable. In view of the many important results likely to come from such a programme—benefitting not only cometary astronomy—it is to be hoped that someone will investigate the further possibilities of 'occultation' astronomy.

I thank Dr G. A. E. Wright for discussions. This work was supported by an Advanced Course Studentship.

## Third discontinuity in the Vela pulsar period

THE period of the Vela pulsar, PSR0833-45, decreased discontinuously by approximately two parts in  $10^6$  near the beginning of October 1975, the third such event observed for this pulsar. The first<sup>1,2</sup> occurred in March 1969, and the second<sup>3</sup> in August 1971.

Since May 1975 pulse arrival-time data have been recorded for a number of pulsars at the NASA Deep Space Station,
